Packaging plays a vital role in containing and protecting food as it moves through the supply chain to extend its shelf life. It is estimated that 37% of the packaging products are made from plastics, which makes plastic the most used packaging material (Rexam, 2011). Plastic packaging represents 26% of the overall plastic market (Plastics Europe, 2015). The domination of plastic packaging in food packaging market is due to their low production cost, mechanical resistance, heat sealability, water & gas barrier properties, and shape flexibility. By 2023, it is expected that global plastic films sheets market will witness a significant growth of USD 146,813.87 million (Market Future Research, 2019). Asia Pacific is the largest market of plastic films, where China, Japan and India are being the main players (Market Future Research, 2019). In Europe, packaging applications represent about 40% of the total plastics demand (European bioplastics, 2014). In USA, approximately 380 billion plastic bags are used every year that is more than 1200 bags/US resident/year. In India, packaging materials account for 25% of the total production of plastics, but it accounts for 52% in terms of consumption. However, only 3% of the plastic waste is being recycled worldwide. The accumulation of these plastic packaging on earth is a major threat to environment due to its non-biodegradability and its impact on health of terrestrial and aquatic animals (Thompson *et al.*, 2009). Recent studies estimate that 31% of the plastic debris in marine environments originates from food and beverage packages. Plastic pollution of the global marine environment is a persistent and pervasive problem, about 8 million tons of plastics has been leaked into the ocean annually, which is equivalent to dumping one garbage truck into the ocean every minute. If no action has been taken, this is expected to increase to two per minute by 2030 and four per minute by 2050 (Jambeck *et al.*, 2015). Considering that 31% of a garbage truck is filled with plastics originating from plastic food and beverage packaging, it becomes clear that food and beverage packaging is an important contributor to the pollution of the marine environment. Thus even a small reduction in the amount of plastic materials used for each package would result in a significant reduction in air and water pollution, improve solid waste disposal and conservation of non-renewable resources (fossil-based plastics). Recently, due to growing concerns about health and environmental protection, there has been a growing interest in developing natural and biodegradable packaging to maintain the postharvest quality of fruits and vegetables (Arnon *et al.*, 2014; Fagundes *et al.*, 2015). Presently, the global biodegradable plastic market represents less than 1% of the overall plastic market but it is expected to grow at a fast pace in the coming years (Markowicz *et al.*, 2019). The development of new biodegradable packaging is a very interesting alternative to reduce the volume of waste from plastic packaging materials. However, large price difference between biodegradable packaging and conventional plastic packaging is the major limitation that will affect the market growth (Future Market Research, 2016). The growth of biodegradable packaging industry depends upon the consumer preference towards environmental friendly products, government policies towards green procurement and use of renewable and bio-based raw products. The research and developments in the area of biodegradable packaging is a key and unique field of exploration within food packaging which possesses enormous commercial and environmental potential.

Biodegradable and Compostable: Definitions and Standards

The term 'biodegradation', 'biodegradable material' and 'composting' are very common but they are frequently misused and misunderstood. The solubility in water is frequently considered as a synonym of biodegradability, and biodegradability as a synonym of compostability. According to the American Society for Testing of Materials (ASTM) and the International Standards Organization (ISO), the degradable plastics undergo a significant change in chemical structure under specific environmental conditions. These changes result in loss of physical and mechanical properties which can be measured by standard methods. The biodegradation of polymers is a very complex process and can occur in a number of ways. Biodegradable polymers undergo degradation due to the action of naturally occurring microorganisms such as bacteria, fungi and algae. "Biodegradable" is defined by ASTM as "Capable of undergoing decomposition into carbon dioxide, methane, water, inorganic compounds, or biomass in which the predominant mechanism is the enzymatic action of microorganisms, that can be measured by standard tests, in a specified period of time, reflecting available disposal condition (ASTM, 2005)." In the European Union (EU), there are no standards for biodegradation of materials, in contrast to composting. It is a general acknowledgment that in nature there is at least one enzyme which is responsible for speeding the breakdown process of chemical bonds of a polymer chain. However, degradation will not occur in an unfavorable environment or the biodegradable material will not degrade within in a short time. Notably, the term "biodegradable" does not imply a fast process. It is, therefore, important to couple the term biodegradable with the specification of the particular environment where the biodegradation is expected to happen, and of the time scale of the process (CEN, 2014).

The EU Directive 94/62/EC has specified that composting of packaging waste is a form of recycling, in which original package is transformed into a new product – 'the compost'. The biological treatment may have a very important role to reach the recovery targets fixed by the Directive. The biological treatment can be aerobic (compositing) or anaerobic (biomethanization). Composting leads to the transformation of waste into carbon dioxide, water and compost, usable for agricultural purposes.

Biomethanization leads to formation of biogas (methane and carbon dioxide) and sludge. The anaerobic sludge is then usually transformed into compost by a subsequent composting step. For this reason, the term 'composting' is used as a synonym of biological treatment of solid waste, covering both aerobic and anaerobic processes. The European Committee of Standardization (CEN) has been appointed by the European Commission with the Mandate M200 to prepare the technical norms to support the EU Directive 94/62/EC. In particular, the group denominated CEN TC261 SC4 WG2 (within the Technical Committee 261, 'Packaging') and prepared the norm EN13432 "Requirements for packaging recoverable through composting and biodegradation – Test scheme and evaluation for the final acceptance of packaging". This standard defines how quickly and to what extent a biodegradable plastic must degrade under industrial composting conditions (Oever *et al.*, 2017). According to the EN13432 standard, compostable material must have following characteristics:

- The packaging material and its relevant organic components are naturally biodegradable (The ability to convert compostable materials into carbon dioxide under the action of microorganisms). This property is measured according to EN 14046 (also published as ISO 14855: biodegradability under controlled composting conditions). To demonstrate complete biodegradability, the level of biodegradation of at least 90% must be achieved in less than 6 months.
- Disintegration (physical fragmentation) and loss of visibility of the packaging material takes place in the final compost, composting measured by testing in laboratory conditions (EN 14045).
- The packaging material has no negative effect on the composting process.
- The packaging material does not negatively influence the quality of the final compost and have low levels of heavy metals.

According to ASTM D6400/D6868 (for compostable plastics) a product or material must meet three key criteria to be certified as compostable:

- Material or product must disintegrate into small fragments but should not be screened out.
- Material or product must convert into CO₂, water and organic matter at an satisfactory rate.
- Finished product must support plant growth and must not leave behind any toxic residue.

There are still no European standards for 'home compostable' and 'soil degradable' packaging. The most common private institutes providing certificates for composting and biodegradation of materials are the European company 'Vincotte' and the U.S. Company 'BPI'. According to various international standards such as EN13432, ASTM D6400 and Green Pla, biodegradable and compostable materials are marked. In an attempt to articulate the conditions under which products will biodegrade, Vincotte offers certifications for the different kinds of environments where products are likely to end up: water and soil. Thus, these products are labeled as 'OK biodegradable SOIL', especially beneficial in agricultural uses, 'OK biodegradable WATER', reducing waste streams in natural fresh water and 'OK biodegradable MARINE' reducing waste in marine water.

Factors Responsible for Biodegradation

Several factors are known to affect biodegradation. The chemical structure of the polymer is most important factor responsible for biodegradation. Polymer characteristics such as nature of the chemical bond, functional group stability, reactivity, hydrophobicity and swelling behavior, flexibility of the chains, crystallinity, hydrophobicity, molecular size, and environmental factors such as temperature, pH of the medium, presence of oxygen, moisture, microorganisms such as bacteria, fungi etc., and enzymes affect biodegradation in its various stages. Therefore, both the biodegradability and the degradation rate of a biodegradable polymer product may be different on the soil, in the soil, in humid climate, in dry climate, in marine water, in surface water, in home composting, in industrial composting or anaerobic digestion (Van Der Zee, 1997; OWS, 2013). Some linkages (amide, ester, urethane, anhydride, orthoesters etc.) of polymers are more susceptible to hydrolysis by hydrolytic enzymes and microorganisms because of flexibility of these polymers to fit into active sites of enzymes. It was observed that the polymer having both hydrophobic and hydrophilic properties have more biodegradability than the polymer having either hydrophobic or hydrophilic properties (Nair and Laurencin, 2007). Two factors affecting the enzymatic degradation of synthetic polymers are the steric configuration of the polymer itself and the nature of the substituents adjacent to the susceptible bond. For example, biodegradation is inhibited by branching of the molecular chain and it was observed that chain branching in polymers like polystyrene and polypropylene cause difficulty in biodegradation. The copolymer composition and morphology play a significant role in biodegradation. The processing conditions such as annealing, sterilization process, storage history, etc., also play significant roles in biodegradation (Joshi and Patel, 2012). Other factors that affect degradation rates are water diffusion, hydration, disruption of van der Waals forces and hydrogen bonds, monomer solubility and diffusion, device geometry and size, erosion mechanism, etc., (Adeosun *et al.*, 2012; Nampoothiri *et al.*, 2010).

Chemistry of Biodegradation

The biodegrading of polymeric material is a complex process and generally take place in two stages (Pillai, 2014). In the first stage, there is depolymerization of the larger molecules of polymeric into the shorter chains while in second stage there is mineralization. Depolymerization of the macromolecules normally occurs outside the organism due to the size of the polymer chain and the

insoluble nature of many polymers. During this step, presence of microorganisms, heat (degradation rate depends on temperature), and humidity are responsible for breaking the carbon bonds of polymer chain. During second step i.e., mineralization, small size oligomeric fragments are transported into cells where they are bio-assimilated by the microorganisms and then mineralized. Second step of biodegradation process begins when shorter chains become energy sources of microorganisms (bacteria, fungi or algae). This process is confirmed as biodegradation in full sense only when carbon compounds become food and microorganisms are transformed into water, biomass or carbon dioxide (Barone and Arikian, 2007). These changes result in a loss of physical and mechanical properties, as measured by standard methods. Polymers may also be nominated as photodegradable, oxidatively degradable, hydrolytically degradable, or those that may be composted, or thermally and mechanically degradable (Jakobek, 2014).

The Mechanism of Biodegradation of Polymers

- Photodegradable polymers: These polymers breaks down (i.e., braking of chemical bonds) under the influence of natural light (photooxidation).
- Oxidatively degradable polymers: These polymers breaks down by oxidation.
- Hydrolytically degradable polymers: These polymers breaks down by hydrolysis.
- Thermally degradable polymers: These polymers breaks down by thermal process.
- Degradable polymers: The polymer whose chemical structure is changed under the influence of moisture and oxygen.
- Biodegradable polymers: These polymers are broken down under the influence of naturally occurring microorganisms.

Biodegradable Polymers and its Classification

Biodegradable polymers are very large molecules having long chain-like structure with high molecule weight, produced by living organisms. They are very common in nature and form the building blocks of plant and animal tissue. Biodegradable polymers are materials that can be broken down by microorganisms (bacteria, fungi, algae) into water, naturally occurring gases like carbon dioxide and methane and biomass.

Biodegradable polymers can be broadly divided into different categories based on the origin of the raw materials (renewable or non-renewable) and the processes used in their manufacture (Fig. 1). Polymers derived from renewable resources (biopolymers) are broadly classified according to method of production, as follows:

Fig. 1 Classification of biodegradable polymers for packaging.

- (1) Polymers directly extracted/removed from natural materials (plants, marine and domestic animals). Examples are polysaccharides (starch, cellulose, chitin, chitosan), protein (whey protein, casein, collagen, soy protein, myofibrillar proteins of animal muscle, etc.).
- (2) Polymers produced by microorganisms or genetically transformed bacteria. The best known bio-polymer types are the polyhydroxyalkanoates (PHAs), mainly polyhydroxy butyrate (PHB) and copolymers of hydroxy-butyrate (HB) and hydroxyvalerate (HV) (Petersen *et al.*, 1999).
- (3) Polymers produced by “classical” chemical synthesis from renewable bio-derived monomers. A good example is polylactic acid, a biopolyester polymerized from lactic acid monomers. The monomer itself is produced via fermentation of carbohydrate feedstock.

In addition to the natural polymers and polymers from renewable resources, man-made synthetic biodegradable polymers developed from non-renewable resources (oil products) have been developed, mostly for biomedical and agricultural applications, but they also have applications in packaging industry (Mitrus *et al.*, 2009). They offer more advantages over natural polymers because they can be tailored to give a wider range of properties and can be made into a degradable material for specific applications. Generalizing, they are biologically inert, readily available and have more predictable properties (Rydz *et al.*, 2015).

According to the European Bioplastics (2015), biopolymers made from renewable resources have to be biodegradable and especially compostable, so they can act as fertilizers and soil conditioners. Whereas plastics based on renewable resources must not necessarily be biodegradable or compostable, the bioplastic materials do not necessarily have to be based on renewable materials, because the biodegradability is directly correlated to the chemical structure of the materials rather than the origin. In particular, the type of chemical bond defines whether and in what time the microbes can biodegrade the material.

The problems associated with renewable biopolymers are threefold: performance, processing and cost. Although these factors are somewhat interrelated, problems due to “performance and processing” are more pronounced with polymers extracted directly from biomass (cellulose, starch, proteins). Conversely, polymers belonging to categories 2 and 3 above, generally perform very well and are easily processed into films using standard plastic techniques, but tend to be expensive compared with synthetic analogs (Petersen *et al.*, 1999).

Polymers Extracted/Isolated Directly From Natural Material (Biomass)

Natural products and natural product derived compounds play an important role in the food packaging industry. The outstanding aspect of natural biopolymers is their wide variety, which gives innumerable opportunities for structural modifications and utilization. Polymers of this category are obtained from plants, marine and domestic animals. Examples are polysaccharides (starch, cellulose, chitin, chitosan), protein (whey protein, casein, collagen, soy protein, myofibrillar proteins of animal muscle, etc.). Nature has a plethora of natural enzymes for degrading natural polymers. Due to their natural origin, all natural polymers are biodegradable because for each action of a polymerase, there is depolymerase that can catalyze the degradation in order to maintain the balance of nature (Khemani and Scholz, 2012; Rydz *et al.*, 2015). The advantageous properties of these polymers are their biodegradability, supplementary nutritional food value, incorporated antimicrobial and antioxidant properties, renewable origin, relatively low cost, prevalence, and the fact that they have no negative impact on the environment like a traditional plastic material (Sam *et al.*, 2015).

(1) Starch

Starch is a promising raw material because of its annual availability from many plants parts such as tubers, seeds, stems and leaves (Chen and Evans, 2005). Starch is a polymeric carbohydrate produced by many plants, such as corn, potato, wheat, rice, barley, oat and soybean. In addition to being staple food, starch has recently gained interest as a renewable and biodegradable plastic (Wang *et al.*, 2009) because of the worldwide environment and resources problems resulted from petroleum-derived plastics (Averous *et al.*, 2000). Starch contains two types of D-glucopyranose polymers: amylose (20%–30%) and amylopectin (70%–80%). Depending on the source, starch has different proportions of amylose and amylopectin. Amylose is a linear polymer of α -D-glucopyranosyl units linked (1–4). These molecules can be comprised of 100 to over 1000 glucose units. Amylopectin is a branched polymer of α -D-glucopyranosyl units containing (1–4) linear linkages and (1–6) linkages at the branch points. Amylopectin is three or more times larger than amylose. Most naturally occurring starches contain approximately 30% amylose; however, specific starches and their properties are determined by the size and amount of each type of polymer molecule present in the material.

Starch is one of the promising biopolymer materials due to biodegradability, non-toxicity, availability, and renewability. It is oil resistance, flexible in nature, oxygen impermeable, heat stable, and water soluble (Krogars *et al.*, 2003). Amylose has the film-forming property of starch (Claudia *et al.*, 2005). Starch can be used to form edible or biodegradable films. Different sources of starch, high amylose starch, modified starch (Mali and Grossmann, 2003; Mali *et al.*, 2006; Roth and Mehlretter, 1967; Wolff *et al.*, 1951) have been used to form self-supporting films by casting from aqueous solution. The starch-based films are tasteless, colorless, odorless, translucent (not transparent), non-toxic, biologically absorbable, semi-permeable to CO₂, and impermeable to release of O₂ (The *et al.*, 2009). They are used in applications where transparency is not required. Starch based films are frequently used in cellophane based barrier laminates to allow heat sealing. These types of laminates are used in pouches for products like cereals and cookies. Starch based trays (rigid or foamed) can be used to pack fruits and vegetables.

Starch based trays are not transparent. A specific type of foamed starch tray is Paperfoam™ and it is mainly used for packaging where product protection is important, e.g., egg boxes, electronic devices. The starch based edible film reduces the microbial growth, control, enzymatic reaction and lowering water activity of packed food products (Wong *et al.*, 1994).

There are many hydrogen bonds between the starch macromolecules, which reduce the movement of these molecules, so the native starch has poor processing ability. Due to the fact that starch film is brittle in food packaging materials, thermoplastic starch can be obtained by the destruction of the granules in the presence of plasticisers under specific conditions. Polyols are the most widely used plasticisers, such as glycerol (Fishman *et al.*, 2000), glycol (Smits *et al.*, 2001; Yu *et al.*, 1996), sorbitol (Wang *et al.*, 2000), xylitol, and sugars; of these, glycerol is the most commonly used plasticiser. Thermoplastic starch (TPS) is a mixture of starch and plasticiser after the gelatinization process. It is hygroscopic; therefore this material is not suitable as packaging for high-moisture and liquid food products. However, it has good oxygen-barrier properties. Blending of starch with polyesters is necessary to improve water resistance, processing properties and mechanical properties. Commonly the starch content of starch based plastics is lower than 50% and the overall bio-based content of these materials depends on the nature of the other components. Glycerol-plasticised thermoplastic starch can recrystallize (retrograde) on storage. In order to prevent retrogradation, some plasticisers containing amide groups were used, such as formamide and acetamide (Ma and Yu, 2004a), urea (Ma and Yu, 2004b) and the formamide/urea mixture (Ma *et al.*, 2004). However, these amide group-containing plasticisers are toxic and would not be allowed in many applications, such as fast food service-ware, food packaging, pharmaceutical and biomedical application. To solve this problem, a nontoxic plasticiser is required. DL-Lactic acid is rated as nutritionally harmless compared to other substances used for derivatisation. DL-Lactic acid will act as a plasticiser. DL-Lactic acid that reacts with starch can be considered as an internal plasticiser. Starch can also be plasticized by genetic and chemical modification or blending with materials like poly vinyl alcohol (PVA), poly(ϵ -caprolactone) (PCL), and others. Thermal and mechanical properties of thermoplastic starch depend on the content of these polymers in the blended plastic (Lu *et al.*, 2009). Starch/PCL blends with glycerol and citric acid as compatibilizers have better properties than plain starch film and show that even small amounts of PCL (10 wt%) allow lowering the glass transition temperature and increasing the water vapor barrier properties (Ortega-Toro *et al.*, 2016a). Serier and Aoufi (2017) reported that the glycerol and DL-lactic acid blended films have better film properties (water vapor permeability, mechanical strength). López *et al.* (2015) prepared packaging bags from thermo-compressed films based on thermoplastic starch modified with talc nano-particles. The strength properties of the film were the best but it did not show better film properties, such as mechanical properties or water vapor barrier as compared to plain starch films (Ortega-Toro *et al.*, 2016b). The acetylated or oxidized arracacha native starch may be used to manufacture biodegradable films. The films produced with acetylated starch present high transparency, moreover, the physicochemical and microbiological tests show that acetylated starch could be used in films for food packaging (Medina *et al.*, 2012). The sugar palm starch, combined with different plasticizer types (such as a glycerol, sorbitol, and glycerol/sorbitol combination) may be used for preparation of biodegradable packaging films. Regardless of plasticizer types, the films demonstrate increased water vapor permeability (WVP) (Sanyang *et al.*, 2015). Starch converted into a foamed material by water steam can be used as packaging material for trays or disposable dishes (Siracusa *et al.*, 2008).

The advantage of these TPS based products is that these products can be composted together with the organic waste. Starch blends are generally compostable and various materials (depending on the other blend components) are also biodegradable in soil, anaerobic digestion installations, fresh water or marine environment. Not all starch blends are allowed for food contact applications and this depends on the presence of blend components that can potentially migrate out of the starch blend. Starch-based thermoplastic materials were used for food wrappings and cups, plates, expanded trays, and other food containers (Rejak *et al.*, 2014). Novamont is one of the leading companies in processing starch-based products using their own starch-based blend (Babu *et al.*, 2013).

(2) Cellulose and derivatives

Cellulose, which is essentially linear polymer of anhydroglucose, is the most abundant natural polymer on earth. In recent times, cellulose has attracted considerable attention as one of the most well-known renewable and ecological raw materials for obtaining environmentally friendly and biocompatible technological products. Biomass produced by photosynthetic organisms such as plants, algae, and some bacteria is made up of cellulose and for that reason it is the most abundant biopolymer on earth (Klemm *et al.*, 2005). As a result, the use of cellulose-based materials in composites has increased over the last few years because of their relative low price compared to conventional materials, their recyclability, and their mechanical properties. Wood pulp remains the most important raw material for the processing of cellulose (Klemm *et al.*, 2005). Wood contains 40%–50% cellulose by weight. Cellulose is unsuitable for film production because it is highly crystalline, fibrous, and insoluble in water. Therefore, cellulose is dissolved in a mixture of sodium hydroxide and carbon disulfide and recast into sulfuric acid to make a cellophane film. Cellophane has good mechanical properties, but it is sensitive to moisture. It is often coated with nitrocellulose wax or polyvinylidene chloride to improve its moisture barrier properties. Coated cellophane is used for baked goods, fresh produce, processed meat, cheese, and candy. Cellophane has good gas barrier properties at low relative humidity. However, its barrier properties are reduced at intermediate and high relative humidities. Cellophane is not heat sealable owing to its non-thermoplastic nature (Petersen *et al.*, 1999). Hemicellulose, the second most abundant plant polymer in the world, is in its infancy as a biomaterial research for food packaging (Grondahl *et al.*, 2006). Cellulose nanocrystals (CNC) are a novel class of nanomaterials with many promising applications. Cellulose nanoparticles have a strong tendency for self-association due to the interaction between surface hydroxyl groups. CNC are obtained in aqueous suspension from strong acid hydrolysis of cellulosic fibers.

(3) Chitin and chitosan

Chitosan is a chitin derivative, and second most abundant polysaccharide found in nature after cellulose. Commercially it is prepared by chemical N-deacetylation of chitin, which is a component of shells from marine crustaceans (shrimp, oysters, crabs, lobsters, and Antarctic krill), fungal cell walls and other biological materials (Andrady and Xu, 1997). The degree of deacetylation and the molar mass of the polymer is one of its most important chemical characteristics, which is the base of the biological properties of chitosan (Rabea *et al.*, 2003). It is structurally almost identical to cellulose. Chitosan is classified as a dietary fiber. It's also a good source of minerals and increases the gastric emptying (Zhao *et al.*, 2011).

As a packaging material, chitosan has many valuable features. The chitosan polysaccharide is non-toxic, biofunctional and biodegradable (Wang, 1992; Shahidi *et al.*, 1999; Jayakumar *et al.*, 2007, 2005, 2006; Jongrattiporn *et al.*, 2001). The chitosan-based film is generally adhesive and cohesive with a smooth surface (Coma *et al.*, 2002) and it has poor solubility with neutral water. Chitosan produces highly viscous products (Peniston and Johnson, 1980) and has the ability to form films without the use of other additives, and it is resistant to heat. Chitosan has good permeability to oxygen and carbon dioxide and excellent mechanical properties (Yam, 2009). Chitosan biopolymer has hypoglycemic and hypolipidemic anti-oxidant activity (Kim and Thomas, 2007; Yao *et al.*, 2008). Furthermore, it also has antimicrobial activity and can therefore be used to extend the shelf life of food and as a component of biodegradable edible films for food. One of the mechanisms of microbial inhibitory effects of chitosan is that it can induce the synthesis of chitinase in plant tissues, degrading microbial cell walls (Lin and Zhao, 2007). The type of solvent used for the formulation of the coating solution of chitosan can also present an antimicrobial effect due to the acid environment created such as the case of acetic acid (Ochoa-Velasco and Guerrero-Beltran, 2014). Chitosan has antifungal properties to various fungi. Some studies have shown that chitosan coatings can effectively reduce the growth of fungi extending the life of strawberries and blueberries (Duan *et al.*, 2011). Chitosan can also act as an excellent carrier of other functional substances. The addition of cranberry leaf extract in the chitosan coating formulation can improve its antimicrobial features. The addition of nisin, garlic extract, potassium sorbate, lysozyme, and many other compounds as antioxidants and preservatives allow for longer storage of products without the development of bacteria and fungi (Youwei and Yinzhe, 2013).

Chitosan membrane is used for coating fresh fruits, in particular, strawberries, berries, and grapes (Ribeiro *et al.*, 2007; Duan *et al.*, 2011; Petriccione *et al.*, 2015). It forms semi-permeable films and when applied as a coating on fruit modifies the internal gas atmosphere of the fruit as well as barrier to water vapor to reduce moisture loss, delays the dehydration of fruits and reduces decaying. De Oliveira *et al.* (2014) studied the effect of chitosan coating on table grapes and observed that the physicochemical and sensory characteristics of fruits were not affected during storage. Han *et al.* (2014) studied the effect of chitosan coating on sponge gourd and observed that the chitosan coating effectively reduce the respiration rate and the weight loss, preserves the strength and visual appearance, retains the ascorbic acid content and total phenolic compounds, and delays the polyphenol oxidase (PPO) activity.

Chitosan is used as food additives in dairy products, cereals, meat and seafood, juice, and eggs (Kerch *et al.*, 2010; Friedman and Juneja, 2010). Chitosan can be blended with different polymers. Joseph *et al.* (2011) reported that the chitosan/PCL blend films had lower water vapor transmission than plain chitosan films. It is expected that fruits and vegetables packaged in this film will have potentially extended shelf life. Massouda *et al.* (2012) reported that the extrusion films with chitosan and DuPont ionomer of ethylene acid copolymer with poly(vinyl alcohol-co-ethylene) may be used for antimicrobial package. Tan *et al.* (2015) produced novel composite film based on chitosan with grapefruit seed extract to pack bread samples and observed that the shelf life of bread samples is two times longer than those packaged using synthetic packaging films. The film also prevents the growth of fungi and bacteria and has mechanical strength and flexibility almost like synthetic polyethylene film (National University of Singapore, 2016).

Proteins

In their native states, proteins can be divided into 2 groups i.e., fibrous proteins and globular proteins. Fibrous proteins are water insoluble and obtained from animal tissues (e.g., casein, whey protein, collagen, gelatin, keratin) whereas globular proteins are soluble in water or aqueous solutions of acids, bases or salts and obtained from plant origin (e.g., wheat gluten, soy protein, peanut protein, corn-zein, cotton seed protein) (Gennadios *et al.*, 1996). The two most common vegetable (globular) proteins used in the production of biodegradable packaging are chickpeas and isolated soy protein. Other vegetable proteins used for packaging are extracted from wheat, pistachios, peas and sunflower (Dean and Yu, 2005). The animal proteins used for the production of biodegradable packaging are albumin, casein, fibrinogen, silk and elastin but these are used on limited scale because of difficulty in processing as these proteins do not melt without decompression, and face difficult to mix with other polymers due to incompatibility (Battacharya *et al.*, 2005).

(1) Whey protein (WP)

Whey protein (WP) is a by-product from the cheese production and is particularly rich in β -lactoglobulin. Whey proteins (20% of total milk proteins) when appropriately processed produce flexible but brittle films (Kaya and Kaya, 2000). WP is capable of forming flexible films, and due to moderate moisture permeability, good oxygen barriers, and good biodegradability they are used as raw material for producing edible films, biodegradable films, or materials for biodegradable packaging (Ramos *et al.*, 2012; Wang *et al.*, 2013). WP is one of the most common and least expensive raw materials used in the preparation of edible films. Plastic films formulated with the use of WP are biodegradable and have a high barrier to oxygen

(Bugnicourt *et al.*, 2010). It can be used as a coating on paper and also on plastic substrates with polymers such as polypropylene (PP), polyvinyl chloride (PVC), and low-density polyethylene (LDPE). The coatings showed good mechanical properties and visual properties, such as excellent gloss and transparency (Ozdemir and Floros, 2008). WP based coatings blended with plasticizers have high barrier properties and moderate moisture permeability (Popovic' *et al.*, 2012; Verbeek and Van den Berg, 2010). The blending of WP with Bio-Flex improves oxygen barrier properties but does not affect the rate of its biodegradation (Cinelli *et al.*, 2014). The nanocomposite films consisting of whey protein isolate (WPI) with zein nanoparticles (ZNP) coated with sodium caseinate can be used as biodegradable food packaging materials (Oymaci and Altinkaya, 2016).

(2) *Corn zein*

Corn zein is the most important protein in corn that has both hydrophobic and hydrophilic properties. It is a prolamine protein found in corn endosperm and therefore dissolves in 70%–80% ethanol (Dickey and Parris, 2002). It has poor mechanical properties, however, can potentially be used for food packing, especially as a protective, impermeable coating, due to its good gas barrier, biodegradation, and biocompatibility properties (Ozcalik and Tihminlioglu, 2013). Films prepared from this protein are used for separating layers of food, such as slices of cheese, and the coating of many products including fruits and vegetables, nuts, meat, and cooked sweets. Furthermore, corn zein films are used to cover food fried in deep fat (for the reduction of fat absorption by the product) (Cutter, 2006). The application of plasticized corn zein coatings on the polypropylene film with a plasticizer such as PEG and glycerol reduced the oxygen and water vapor permeability (Tihminlioglu *et al.*, 2010). Ozcalik and Tihminlioglu (2013) observed that PP film coated with a corn zein nanocomposite successfully improve the barrier and mechanical properties of final packaging material. Corn zein films have also shown an ability to reduce moisture and firmness loss and delay color change (reduce oxygen and carbon dioxide transmission) in fresh tomatoes (Park *et al.*, 1994). Corn zein based films with oleic acid, nanocarbonate and glycerol as a plasticizer show the possibilities of using the material with nanocarbonate to pack food products (Ribeiro *et al.*, 2015).

(3) *Wheat gluten (WG)*

Wheat gluten (WG) is a general term for water-insoluble proteins of wheat flour which is composed of a mixture of polypeptide molecules, considered to be globular proteins. Cohesiveness and elasticity of gluten give integrity to wheat dough and facilitate film formation. WG contains the prolamine and gluten fractions of wheat flour proteins, typically referred to as gliadin and glutenin, respectively. While gliadin is soluble in 70% ethanol, glutenin is not. Edible films can be formed by drying aqueous ethanol solution of WG. Addition of plasticizer such as glycerin in WG films is necessary to improve film flexibility (Gennadios *et al.*, 1996). However, increasing film flexibility by increasing sorbitol content reduces film strength, elasticity and water vapor barrier properties. Tensile strength of gluten films can be improved by using a cross-linking agent such as glutaraldehyde, or heat curing at 80°C (Gennadios and Weller, 1990; Koelsch and Labuza, 1992). El-Wakila *et al.* (2015) produced nanocomposites consisting of WG, cellulose nanocrystals (CNC), and TiO₂ nanoparticles, and observed that the suspension blend has excellent antimicrobial activity and good mechanical properties and can be used to coat commercial packaging, such as unbleached Kraft paper. Ferreira *et al.* (2012) observed that the biopolymers obtained by mixtures of WG and glycerol (plasticizer) could be used for producing barrier materials. Rafieian *et al.* (2014) showed that carboxylated cellulose nanocrystals (CCNC) can be used as reinforcing fillers for WG composite packaging films. Cho *et al.* (2010) prepared a laminated film with WG, plasticizer (glycerol) and polylactide (PLA) and observed that the resulting laminated film has very good oxygen barrier properties and low water vapor transmission rate. Türe *et al.* (2012) reported that the antimicrobial film consisting of glycerol-plasticized wheat gluten and potassium sorbate has antimicrobial activity against *Aspergillus niger* and *Fusarium incarnatum*.

(4) *Soy protein*

Soy protein is the protein that is found in soybeans. Soy protein isolate (SPI) is a highly purified form of soy protein made up of 90% protein on a moisture-free basis. The protein content of soybeans (38%–44%) is much higher than the protein content of cereal grain (8%–15%). Most of the protein in soybeans is insoluble in water but soluble in dilute neutral salt solutions (Kinsella and Phillips, 1979). Soy protein consists of two major protein fractions referred to as the 7S (conglycinin, 35%) and 11S (glycinin, 52%) fraction. Both 7S and 11S contain cysteine residues leading to disulfide bridge formation and processing is, therefore, similar to wheat gluten with similar mechanical properties. SPI may be used to prepare edible and biodegradable packaging films. The films obtained from SPI exhibit excessive friability, therefore, plasticizer such as glycerol are added to improve its performance (Kokoszka *et al.*, 2010). Carpiné *et al.* (2015) concluded that the emulsion-based edible films made of SPI, virgin coconut oil, soy lecithin, and glycerol (plasticizer) can be used for food packaging applications. González and Igarzabal (2013) prepared biodegradable bilayer films from SPI and polylactide (PLA), and observed that the resulting film has high transparency and strong adhesion between layers. Moreover the PLA layer considerably increases the mechanical properties of the films relative to those of pure SPI films. The bilayer film can be used as a biodegradable material for active food coatings.

(5) *Collagen*

Collagen is a flexible polymer but due of its complex helical and fibrous structure, it is very insoluble and difficult to process. It is a major constituent of skin, tendon and connective tissues and is most prevalent and widely distributed fibrous protein in the animals. Collagen is the basic raw material for gelatine production. The characteristic features of gelatin are high content of the amino acids- glycine, proline and hydroxyproline. Gelatin also has a mixture of single and double unfolded chains of hydrophilic character (Ross, 1987). Gelatine is produced via either partial acid or alkaline hydrolysis of

collagen. Such treatments disrupt the tight, helical structure of collagen and produce water-soluble fragments that may form stiff gels, films or light foams. Gelatine is a very processable material, but it is extremely moisture sensitive. Therefore, for prolonged use in packaging, research is needed for the chemical modification of gelatine to improve moisture sensitivity (Claus, 2000).

(6) *Casein*

Casein is a milk-derived protein which do not dissolve directly in water, but show approximately 50% weight gain after 24 h of immersion. It is easily processable due to its random coil structure. Upon processing with suitable plasticizers at temperatures of 80–100°C, materials can be made with mechanical performance varying from stiff and brittle to flexible and tough. Casein is highly stretchable making them suitable for film blowing. In general, casein films have an opaque appearance.

(7) *Keratin*

Keratin is the cheapest protein which is non-sensitive to relative humidity. It can be extracted from waste material such as hair, nails and feathers. Due to its structure and a high content of cysteine groups, keratin is also the most difficult protein to process. After processing, a fully biodegradable, water-insoluble-plastic is obtained. However, mechanical properties are still poor compared to the other proteins.

Microbial Polymers Produced by Microorganisms or Genetically Transformed Bacteria

Many bacteria accumulate these polymers as a source of energy and as a carbon source. Genetic transformation of bacteria offers unique opportunities to create non-natural analogs of biopolymers and gives the possibility for further polymer modification (Kim *et al.*, 2015). Different composition units depend not only on the carbon source and type of microorganisms, but also on the dilution rate, the carbon to nitrogen ratio, time, and temperature (Hartmann *et al.*, 2004; Kim *et al.*, 2007). This group includes Polyhydroxyalkanoates (PHAs) and bacterial cellulose (BC).

Polyhydroxyalkanoates (PHAs)

Polyhydroxyalkanoates (PHAs) belong to the polyesters, naturally produced by microorganisms as a carbon storage source. More than 300 different microorganisms are known to synthesize and accumulate PHAs (Lee *et al.*, 1999). A wide variety of mechanical properties, from hard crystalline to elastic, are some of the main advantages of PHAs and the properties depend on the compositions of monomers (Bugnicourt *et al.*, 2014; Rudnik, 2013). PHAs also exhibit printability, flavor and odor barrier, heat sealability, grease and oil resistance, temperature stability, and are easy to dye, which improve its applications in the food industry (Tripathi *et al.*, 2015). Plackett and Siro (2011) described 150 different monomer types of this polymer group. PHAs are biodegradable and as such they can be used for food packaging. To expand the range of materials with food packaging applications, some modification of PHAs has been developed. These strategies include inter alia, chemical or enzymatic modification, preparation of blends and composites, and obtaining functional multilayer films (Koller, 2014). Medium-chain length PHAs can be applied as biodegradable cheese coatings, disposable diapers, fast food service wares, and single-use medical devices (Katiyar *et al.*, 2015a). Poly(3-hydroxybutyrate) (PHB) is the main and the best known representative of the PHA family. PHB is 100% biodegradable and it has similar physical properties with polypropylene (PP). PHB is a polymer of 3-hydroxybutyrate and are intracellular granules produced by prokaryotic organisms as energy and carbon storage during starvation. Bucci *et al.* (2005) compared the properties of PHB and Polypropylene (PP) jars and observed that PHB has 50% lower deformation value than PP but during refrigeration PHB exhibit poor performance than PP. This does not restrict the use of PHB in food packaging and results proved that PP could be substituted by PHB for packaging of fat rich products during refrigeration. The low moisture vapor permeability feature of PHA is very useful in packaging (Katiyar *et al.*, 2015b) and it was observed that the water vapor permeability coefficient of PHA is similar to poly(ethylene terephthalate) (PET) (Koller, 2014). Another important representative of PHAs are PHB copolymers: poly(hydroxybutyrate-co-hydroxyvalerate) (PHBV), poly(hydroxybutyrate-co-hydroxyhexanoate) (PHBHx), poly(hydroxybutyrate-co-hydroxyoctanoate) (PHBO), poly(hydroxybutyrate-co-hydroxyoctadecanoate) (PHBOD), and poly(3-hydroxybutyrate-co-4-hydroxybutyrate) (P3HB4HB). A certain amount of those copolyesters have attracted industrial interest and were commercialized. PHBs are highly crystalline, brittle and have a high melting point, while PHBVs are more flexible, tougher, and degrade easier when discarded into the natural environment (Katiyar *et al.*, 2015a). Copolymer P3HB4HB has better processing properties than PHB and its mechanical properties are adjustable i.e., it has gained interest in biodegradable food packaging.

The blending of synthetic and natural polymers can have a significant impact on the physical properties and biodegradability of PHAs. Josta and Kopitzky (2015) observed that the blending of PBHV (20%–35% concentration) with Polylactic acid (PLA) improves the mechanical and barrier properties of the obtained material. Boufarguine *et al.* (2013) reported that the blending of PLA with small amount of PHBV (10%) improves the barrier properties and increase elongation at the break point. PLA/PHB blends were used as a matrix in nanocomposite films with synthesized cellulose nanocrystals (CNCs) or surfactant modified cellulose nanocrystals (s-CNCs). s-CNCs as bio-based reinforcements contribute to enhancing the interfacial adhesion between PLA and PHB. Low cost, suitable mechanical properties, high stiffness, low density, and biodegradability show that this material is ideal for food packaging applications (Arrieta *et al.*, 2014). Cunha *et al.* (2016) used two different biodegradable commercial polyesters poly(butylene adipate-co-terephthalate) (PBAT) and poly(butylene sebacate-co-terephthalate) (PBSeT) in the preparation of blends with PHBV and observed that the resulting film has good properties for food packaging, namely tear resistance,

water vapor permeability (WVP), and sealability. Kwiecień *et al.* (2016) observed that the blending of oxidized short-chain polyethylene (OXPE) with PHB improves the mechanical properties of the prepared polymeric material.

The high cost of PHA restricts its commercial use but blending of polymer material with cheap fillers and other additives not only reduces the cost but also improves its properties (e.g., viscoelasticity). Cunha *et al.* (2014) transformed brewers' spent grain (BSG) into brewers' spent grain fibers (BSGF), which were then used as fillers in bio-based composites. BSG is a brewing industry by-product, representing around 85% of the total by-products generated. BSG contain about 17% cellulose, 28% noncellulosic polysaccharides, chiefly arabinoxylans, and 28% lignin. Use of BSGF as a natural filler into the PHA matrix can reduce the cost and improve the viscoelastic properties of the final material. The addition of jute fibers to the biodegradable polymer composites has attracted attention in regards to lowering the cost, renewable nature, and reduction of energy requirements for processing. Commercially available PLA/P3HB4HB blends were used as a matrix in bio-based composites with jute fibers (Musiał *et al.*, 2015). Distiller's dried grains with solubles (DDGS) are a low-cost co-product of the corn-ethanol fuel industry. Use of DDGS as a filler to the PHA matrix seems to be a good solution in the reduction of the composites' cost, but also in the utilization of waste products (Hong, 2014). Kovalcik *et al.* (2015) concluded that the blending of PBHV with lignin decreases diffusion of oxygen and carbon dioxide and resulted stable viscoelastic properties of composed film.

Fabra *et al.* (2013) observed that the use of corn zein as nanostructured interlayers in multilayer PHBV-based films significantly decrease the oxygen permeability values of composed film. Inorganic or organic nanofillers in the nanocomposites based on PHAs may efficiently modify their crystallization behavior, morphology, stability, rate of biodegradation, mechanical, barriers, and thermal properties of the composed film (Khosravi-Darani and Bucci, 2015).

Bacterial cellulose

Bacterial cellulose (BC) is obtained by microbial fermentation in static or agitated cultures (Stoica-Guzun *et al.*, 2013). The use of antibacterial packaging can significantly reduce the use of preservatives in food products. BC based materials has attracted great attention due to its antibacterial properties and low cost (Gao *et al.*, 2014). BC produced by *Acetobacter xylinum* is widely used in food processing as it possess better properties than cellulose from plants (higher water holding capacity, higher tensile strength, distinctly soft texture, and high fiber content).

BC fibers can be used in combination with PVA and the prepared product can be used as packaging materials as it possesses better mechanical strength and biodegradability but unfortunately have high moisture sensitivity (Stoica-Guzun *et al.*, 2011). Due to its high moisture sensitivity, only few reports of applications of BC/PVA in the food packaging industry were observed. Jipa *et al.* (2012) reported that the multilayer films (two external defrost BC membranes and an inner layer containing sorbic acid) can be used as active packaging material with controlled release of an antimicrobial agent. BC can also be used for the preparation of nanocomposite materials with PCL and the obtained film showed good thermal stability and better mechanical properties than PCL (Figueiredo *et al.*, 2015).

Polymers Produced by Classical Chemical Synthesis From Renewable Bio-Based Monomers

It is possible to get a large range biopolyesters by chemical synthesis. The previous packaging materials can be replaced by new types derived from renewable monomers, provided it is economically viable (Berezina and Maria Martelli, 2014). The most famous of this group biopolymer is polylactic acid (PLA).

Poly(lactic acid) (PLA)

PLA is biodegradable thermoplastic linear polyester having similar properties as of polystyrene. Lactic acid, the monomer of PLA, may easily be produced by fermentation of carbohydrate feedstock. The carbohydrate feedstock may be agricultural products such as maize, wheat or alternatively may consist of waste products from agriculture or the food industry, such as molasses, whey, green juice etc., (Garde *et al.*, 2000; Sodergard, 2000). PLA derived from renewable resources, for example, corn, wood residues, or other biomass, is of current interest not only because of the need to ultimately replace many petroleum-based polymers but also because of their useful physical and mechanical characteristics (Haugaard *et al.*, 2003; Frederiksen *et al.*, 2003). Specific benefits of PLA in packaging applications are its transparency, gloss, stiffness, printability, biodegradability, GRAS status, processability and excellent aroma barrier. An antimicrobial packaging system based on PLA would be superior to other antimicrobial system due to its comparable cost, effective antimicrobial activity, few regulatory concerns, and environmental friendliness. The properties of the PLA material are highly related to the ratio between the two monomers (L or D) of the lactic acid. PLA is approved for direct contact with food (NatureWorks, 2016a) and is applied in a range of packaging products (NatureWorks, 2016b). Zhou *et al.* (2016) proposed a method to fabricate super-robust PLA barrier films, which has properties of high efficiency gas barriers, high strength and toughness. PLA is mainly processed into thermoformed pads and containers for packing and serving food, films, transparencies and bottles and other packaging blown, but also mixed with other bio-based and or biodegradable polymers to improve stiffness and strength and to reduce costs. The addition of nanoclay particles to PLA (PLA 3051D) enhances the degradation rate of composite materials (Rapacz-Kmita *et al.*, 2013). A fabric produced from PLA provides a silky feel, durability and moisture management properties. There have been developments in Europe and North America that have involved the use of PLA-based packaging for supermarket products. A few major companies like Nature works LLC, Purac (the Netherlands), Galatic (belgium), Cargil (USA) and several Chinese companies are successfully producing PLA with specification from biomedical applications. The company KHS is using SiOx

technology (multi barrier layer) to produce PLA bottles with excellent barrier properties (reduces moisture vapor transmission rate by 60%), otherwise, it is not possible to use PLA for packaging of soda (Klages, 2013). PLA containers have been used for packaging foods such as Biota™ PLA bottled water, Noble™ PLA bottled juices, and Dannon™ yogurts. The containers meet German and EU food grade requirements.

Synthetic Polymers Produced From Fossil Resources

Synthetic polymers have more predictable properties and the source of raw materials used to obtain such polymers is more readily available (Rydz *et al.*, 2015). The methods commonly used to manufacture synthetic biodegradable polymers are ring-opening polymerization (ROP) for synthesis of polyesters such as PCL, traditional polycondensation reactions for aromatic or aliphatic-aromatic (co)polyesters, or alkaline hydrolysis of poly(vinyl acetate) to PVA. Postpolymerization modification (physical or chemical) leads to synthetic derivatives of common polymers.

Polyvinyl alcohol (PVA)

PVA is a water-soluble and biocompatible polymer that is obtained from poly(vinyl acetate) through alkaline hydrolysis. PVC was one of the first polymers to be used in food packaging applications, and it replaced many traditional materials (glass, paper, cardboard). PVC's toughness combined with good clarity and resistance to oils and other substances makes it suitable for making blow-molded bottles. Flexible PVC film has found wide acceptance for food preservation. These materials have both 'stretch' and 'cling' properties; therefore, they are suitable for the hand wrapping of fresh produce. These materials can also be heat sealed (Leadbitter, 2003). The very low permeability of this polymer to gases (O₂ and CO₂) makes its wide application in food packaging, such as water-soluble packaging films. However, the tendency to absorb moisture limits its use under high moisture conditions. To improve its properties, PVA could be blended with other polymers, for example, food additives such as citric acid, succinic acid, and tartaric acid (Birck *et al.*, 2014). PVA blended with Poly(3-hydroxybutyrate) (PHB) can be used in the packaging industry (Olkhov *et al.*, 2003). Bonilla *et al.* (2014) studied the mechanical, water vapor barrier, and antimicrobial properties of PVA/Chitosan films for its use in food packaging. Musetti *et al.* (2014) investigated active packaging with grapefruit seed extract (GSE) and PVA for food packaging applications. Gaikwad *et al.* (2016) investigated active films from apple pomace and PVA for antimicrobial activities during food packaging.

Poly glycolic acid (PGA)

Polyglycolide (PGA) is another polymer that can be produced not only from petrochemicals, but also from renewable derived monomers. PGA is rigid simplest linear hydrolyzable aliphatic polyester with high crystallinity and barrier properties against carbon dioxide and oxygen. It has a high melting point (220–225°C) and excellent mechanical properties due to its high crystallinity (Vroman and Tighzert, 2009; Daniela and Ovidiu, 2012). PGA has vital advantage of degradability as it loses its strength within 1–2 months when hydrolyzed and loses mass within 6–12 months (Daniela and Ovidiu, 2012). Therefore, in packaging applications, PGA is used as protective layer in multilayer packaging systems, such as PET bottles for carbonated soft drinks and beer (Coles and Kirwan, 2011). The Kureha Corporation owns patents that protect the production process of multi-layer films and sheets for cups, daily dishes, or pizza trays (Kureha Corporation, 2010, 2011). According to the Kureha Corporation website, the biodegradation of PGA resin Kuredex occurs in compost over one month and is considered safe for composting because its degradation product is a natural metabolite – glycolic acid (Kureha Corporation, 2016).

Polycaprolactone (PCL)

Polycaprolactone (PCL) is synthetic biodegradable polyester which is produced from crude oil and biodegradable thermoplastic polymer. It has a good resistance to water, oil, solvent and chlorine (Alp *et al.*, 2011; Nafisa *et al.*, 2015). PCL crystallinity indirectly depends on the molecular weight i.e., increase in molecular weight tends to decrease its crystallinity (Alp *et al.*, 2011). At room temperature, PCL is a semi-rigid material has a modulus in the range of low-density polyethylene (LDPE) and high density polyethylene (HDPE). Enzymes and fungi easily biodegrade PCL. To improve the degradation rate, several copolymers with lactide or glycolide have been developed (Vroman and Tighzert, 2009). Co-polymers of caprolactone with DL-lactide have yielded materials having high rate of degradation (Daniela and Ovidiu, 2012). PCL has a wide range of application area, such as packaging, medical implant, and controlled drug delivery system.

Forms of Biodegradable Packaging

Biodegradable packaging is produced in several different forms to adapt to the requirements for packaging and storage of various products currently the most biodegradable gels, films, bags, boxes with lids and trays.

Biodegradable Gel

The gels are commonly used to prevent microbial contamination, such as a hydrogel, the hydrogel chemical and polymeric network (IPN) (Farrisa *et al.*, 2009). There is no visible positive effects of using impregnating gel on quality of lettuce, while, use of protective gel on fruits of pepino has positive effect on maintaining its beta-carotene content (Schreiner *et al.*, 2003). It was observed that the hydrogels prepared from combination of various polymeric materials reduced the shelf life of certain fruits, probably due to migration of water from the surrounding area (Garcia and Barrett, 2002). White extruded ginseng extract has good potential to maintain the concentration of antioxidants if used together with biodegradable stretch film (Rico *et al.*, 2007).

Biodegradable Films

Biodegradable films are designed with the intention of replacing the polyethylene (PE) film used for different purposes. Biodegradable films have better properties than traditional non-degradable plastics. They are resistant to moisture, warm organic materials for a period of several weeks or even months without changes in physical properties. This allows greater flexibility composting program. The permeability of biodegradable film for oxygen and carbon dioxide showed that the films with low permeability negatively affect the quality of the packed fruits. However, when the permeability of the biodegradable films is in-line with the respiration rate of the fruit, then it results into prevention of contamination by microorganisms and insects, which ultimately have positive effect on the durability and quality of the produce (Muratore *et al.*, 2005).

Biodegradable Bags

The biomaterial used for production of biodegradable bags is polyester. These bags are 100% biodegradable, safe to use for storage and have largest application in food industry. The use of natural raw materials improves the physical properties of this product. Biodegradable bags are strong, flexible, resistant to breakage and damage, and resistant to moisture and temperature changes because of its composition. After use, these bags are decomposed within soil or in the compost to carbon dioxide and water, over a period of several weeks, and also do not reduce the value of the resulting compost, which makes these bags substantially different from previously known polyethylene (Nampoothiri *et al.*, 2010).

Biodegradable Boxes With Lids

Box with a cover made of bi-oriented polystyrene, produced from corn. Such packaging is biodegradable after 47 days, depending on the conditions, and the process and it does not release harmful substances into the environment. It is crystal clear, allowing better visibility of contents, and is resistant to grease and withstands temperatures from -60°C to $+80^{\circ}\text{C}$.

Trays for Fruits and Vegetables

It was found that salad, and sliced broccoli, tomatoes, sweet corn and blueberries can be successfully kept in biodegradable trays of pulp wrapped in foil packaging of poured caprolactone. Such patches are resistant to moisture but brittle. Correspond to the products during freezing them does not change their structural properties well (Makino and Hirata, 1996).

Nanotechnology Functionality

The problems associated with biodegradable polymers are threefold: performance, processing and cost, although these factors are somewhat interrelated. The problems due to performance and processing are common to all biodegradable polymers in spite of their origin (Scott, 2000). In particular, brittleness, high gas and vapor permeability, poor resistance to prolonged processing operations have strongly limited their application. The application of nanotechnology to these polymers may open new possibilities for improving not only the properties but also the same time the cost-price-efficiency (Sorrentino *et al.*, 2007). Nanotechnology is generally defined as the creation and utilization of structures with at least one dimension in the nanometer length scale (109 m). These structures are called nanocomposites and could exhibit modifications in the properties of the materials or create novel properties and phenomena to the materials. To achieve these modifications, a good interaction between the polymer matrix (continuous phase) and the nanofiller (discontinuous phase) is desired (Peelman *et al.*, 2013).

There is growing interest in the incorporation of nanotechnology to enhance the functionality of food packaging for fresh fruit and vegetables. The packaging with antimicrobial compounds such as nano-titanium dioxide and nano-argentum inhibited fruit respiration and decay in Chinese bayberry (Wang *et al.*, 2010). Nano-zinc oxide inhibited ethylene production in fresh-cut apples (Li *et al.*, 2011), while chitosan coatings containing a nanoemulsion of mandarin essential oil aided in the preservation of green beans when combined with both high pressure and pulsed light processing treatments (Donsi *et al.*, 2015). The nanocomposite films consisting of whey protein isolate (WPI) with zein nanoparticles (ZNP) coated with sodium caseinate can be used as biodegradable food packaging materials (Oymaci and Altinkaya, 2016). Corn zein based films with oleic acid, nanocarbonate and glycerol as a plasticizer show the possibilities of using the material with nanocarbonate to pack food products (Ribeiro *et al.*, 2015). De Moura *et al.* (2012) reported that

the thin film created by hydroxypropyl methyl cellulose (HPMC) and silver nanoparticles' (AgNPs) matrix has antibacterial properties with respect to *Escherichia coli* and *Staphylococcus aureus* and can be used for applications in food packaging. Rodríguez *et al.* (2014) showed that nanocomposites with antimicrobial activity based on cellulose acetate, modified montmorillonite (Cloisite30B), thymol as a natural antimicrobial component, and triethyl citrate as a plasticizer are really promising for use in manufacturing food-packaging materials.

When bioplastics are mixed with nanoclay particles, the resulting nanocomposites exhibit improved barrier properties compared with the pure bioplastics, and after their use can be composted and returned to the soil. Nanoclay-composites have been developed for potential use in a variety of food packaging applications and some products are already available for the consumer. Other nanomaterials can be utilized including nanoparticles, nanofibers and nanowhiskers (Sorrentino *et al.*, 2007; Robinson and Salejova, 2010). Introduction of the dispersed clay layers into the polymer matrix structure greatly improves the overall mechanical strength and barrier properties of the material, making the use of nanocomposites films more practical for industry (Sorrentino *et al.*, 2007).

Consumers have shown major concerns with use of nanotechnology in food packaging, including the potential contamination of foods from the release of harmful substances such as silver via migration from packaging (Su *et al.*, 2015). Unless addressed, these concerns may restrict the widespread adoption of this technology.

Potential Applications of Biodegradable Packaging

Research and developments in the biodegradable packaging have been increased in the last decade due to environment pollution issues but these packaging are still rarely seen in the market. Packaging industry and food manufacturers are currently testing biodegradable packaging materials for food. In this section, potential bio-based and biodegradable packaging materials are discussed for packaging of fruits and vegetables only. These suggested materials should not be used directly but these need further optimization.

Fruits and vegetables remain as living tissue until they are consumed fresh, cooked or processed. As soon as the fruit or vegetable is harvested, there is increase in the respiration rate of these living tissues, resulting in metabolic loss which ultimately takes the fruit or vegetable to a gradual maturation and eventual senescence. In fresh-cut fruits and vegetables, the wounding of tissues leads to texture breakdown, development of off-flavor and brown discolouration on the cut surface. In the packed fruits and vegetables, there is continuous change in concentration of carbon dioxide, oxygen, water and ethylene. Controlled respiration of these living tissues would improve storability and extend the shelf life of fresh and fresh-cut fruits and vegetables. Several packing material like LDPE, HDPE, PP, LDPE with thin perforation, expanded (foamed) Polystyrene, shrink films, cling films, netted bags, PET, molded pulp trays, CFB boxes, kraft paper etc are presently used for packaging of fruits and vegetables. The net stocking carriers can be made from biobased material for packaging of fruits and vegetables. The properties of PLA based material matches with the requirement for packaging of mushroom (High water vapor permeability, low gas permeability) (Haugaard and Festersen, 2000). The other possible biobased material used for packaging of fruits and vegetables are perforated PFA, cellulose acetate, cellophane films (for wrapping), starch based trays. Edible coatings may contribute to extend the shelf-life of fresh and fresh-cut produce by regulating the transfer of moisture, oxygen and carbon dioxide; by retaining the aroma and taste compounds in a food system, and by improving the mechanical handling property of foodstuff (Baldwin *et al.*, 1996; Park, 1999). Edible coatings may also be used to improve structural integrity of frozen fruits and vegetables and preventing moisture absorption and oxidation of freeze-dried fruits or vegetables (Baker *et al.*, 1994; Baldwin and Baker, 2002; Olivas and Barbosa-Cánovas, 2005; Park *et al.*, 2005). In addition, edible coatings can carry active ingredients such as antibrowning agents, colorants, antioxidants, antimicrobials, nutrients, flavors and spices to further enhance food stability, quality, functionality and safety (Krochta *et al.*, 1994; Krochta and De Mulder-Johnston, 1997; Debeaufort *et al.*, 2000; Min and Krochta, 2005). Besides this, edible coatings may replace, plastic packaging to some extent by natural and biodegradable substances and their use could lead to reduction in overall packaging requirements and waste disposal problems.

Commercial Application of Biodegradable Packaging

The markets for biodegradable polymers are expanding because of significant developments in terms of novel design strategies and engineering. Presently, there are many research institutions and private companies that are manufacturing polymers based on natural reproducible resources, which including: Bioplast™ (Biotec GmbH, Germany), BAK-1095 and BAK-2195 (BASF and Bayer AG, Germany), Ecoplast™ (Groen Granulaat, Canada), Eco™ (National Starch and Chemical Company, USA), Celgreen™ CA-BNE (Daicel Chemical Industries, Japan), EverCorn Resin™ (Japan Corn Starch, Japan), Mater-Bi™ (Novamont S.P.A., Italy), Novon (Warner-Lambert Co., USA), Solanyl™ (Rodenburg Biopolymers B.V., the Netherlands), Biopac™ (Biologische Verpackungssysteme, Germany), Bioceta™ (Tubize Plastics, France). The many other companies which are manufacturing biodegradable polymers include some names like, Biocell (France), Plantic Technologies Ltd (Switzerland), NatureFlex Innovia Films (United Kingdom), New Greensack (Convex Plastics, Italy), Corbion N.V. (Netherlands), NatureWorks LLC (U.S.), Biome Technology PLC (U.K.), Bio-on (Italy), Kaneka (Singapore), Meredian (USA), Mitsubishi Gas Chemicals (Japan), PHB Industrial S/A (Brazil), Shenzhen O'Boer (China), Tephra (USA), Tianan Biological Materials (China), Tianjin Green Biosciences (China), Yikeman Shandong (China) and others.

BASF, a world leader in the chemical and plastic industry, is working on further development of biodegradable plastics based upon polyester and starch. 'Eco-flex' is a fully biodegradable plastic material that was introduced to consumers by BASF in 2001. The material is resistant to water, grease, hygienic for disposable wrapping, decompose in normal composting systems. Consequently, Eco-flex has found a number of suitable applications as a packaging wrap. Environmental polymers (Woolston, Warrington, UK) has also developed a biodegradable plastic material, known as 'Depart', the polyvinyl alcohol (PVA) product is designed for extrusion, injection molding and blow molding. 'Depart' features user-controlled solubility in water that is determined by the formulation employed. Examples include hospital laundry bags which are washed away, allowing sanitary laundering, wrap for disposable food service items, agricultural products and catheter bags. Biotec (Emmerich, Germany) has three product lines of thermoplastic starch (TPS) which include Bioplast® granules for injection molding, Bioflex® film, and Biopur® foamed starch (Mohanty *et al.*, 2000).

Twenty-four companies are known to be involved in PHA production and applications globally. The most famous company that produces PHA and has received many awards for environmental protection efforts is Metabolix Inc. (USA). The P3HB4HB based copolymers produced by Metabolix Inc, USA is known as Biopol™. Manufacture of blow-molded bottles using Biopol for packaging shampoo was started by Wella AG (Darmstadt, Germany) (Mohanty *et al.*, 2000). Biomer (Germany) is producing PHB using *Alcaligenes latus*, in which accumulation of PHB can receive over 90% of the cell dry mass. PHB obtained that way is used for manufacturing bullets, pens, combs, and so on. The Tsinghua University in Beijing, China, uses *Aeromonas hydrophila* in the production of PHBHx in collaboration with the Guangdong Jiangmen Center for Biotech Development, China; KAIST, Korea, and Procter & Gamble, USA. Recently, Procter & Gamble, USA have begun to develop a large range of polyhydroxybutyrate co-hydroxyalkanoates, which are trademarked as 'Nodax'. Jiangmen Center for Biotech Development, China produces films, flexible packaging, thermoformed articles, coated paper, and other items using Nodax. Tianjin Green Bioscience, China and Metabolix, USA used *Ralstonia eutropha* and recombinant *E. coli* to produce P3HB4HB. *Ralstonia eutropha*, which accumulates 80% PHBV in the cells was used to the model process of PHBV production with high efficiency. Ningbo Tianan, China, developed this process in collaboration with the Institute of Microbiology, affiliated with the Chinese Academy of Sciences (Chen, 2010). Mater-Bi ZI01U/C (biodegradable and compostable bio-based plastic produced by Novamont) was used as a matrix to blend with PHA and bacterial biomass (Scaffaro *et al.*, 2012). Eco Cortec is manufacturing different biodegradable polymers for their application in packaging industry (Table 1).

Polyglycolide and PLA are manufactured under different trade names for various applications by a number of firms. The containers meet German and EU food grade requirements. Some of the important firms that manufacture PLA are Cargill Dow Polymers, the largest producer of PLA resins (NatureWorks PLA), Mitsui Chemical Inc. (Lacea), Schimadzu Corporation (Lacty), Hygai (PLA), Chronopol (Heplon, industrial developmental), Alkermes (Medisorb), Birmingham polymers [poly(L-lactide), poly(DL-lactide) PLAGA], Neste [poly(L-lactide), industrial developmental], Purasorb (PLA, Purasorb, PD, Purasorb, PDL, PURAC), Boehringer

Table 1 Commercial biodegradable packaging material by Eco Cortec

Trade name	Properties
Eco Film®	Certified compostable per ASTM D 6400; 300% stronger than LDPE; High and low temperature stable; heat-sealable, convertible, laminations; Biodegrades rapidly in soil (within 45 days); Elastic and visually attractive material; Accepts printing for marketing and identification
Eco Film® Cryogenic film	Certified by BPI, Din Certco per ASTM D 6400; Specific Eco Film® formula for frozen goods; does not become brittle at extremely low temperatures; all the benefits of Eco Film®; ideal for frozen packaging
Eco Works® Premium films & bags	Certified compostable per ASTM D 6400 and DIN CERTCO; Meet proposed USDA definition of Biobased; New formula Eco Works® 70 has been tested for biobased content at Iowa State University and has a completed BEES environmental profile for "Durable Films"; Certified and approved for Food Contact (Faculty of Food Technology and Biotechnology Zagreb, Croatia); 300% stronger than LDPE; more rigid than Eco Film® (allows handle bags)
Eco Wrap® Compostable stretch film	Up to 60% better yield per roll; Wraps 60% more pallets than standard stretch film; perfect for frozen food & medical; does not become brittle; applied with the same stretch equipment; withstand 400% pre-stretch; accepts printing
Eco-Corr® VpCI biodegradable/compostable films and bags	100% Biodegradable per Din V 54900; BPS Certified; offers superior strength compared to LDPE; heat and water stable; Once exposed to a compost environment Eco-Corr® will biodegrade rapidly with no harmful effects to the environment
Eco-Corr® ESD Compostable Films and bags	Meets requirements for compostability; combines all the benefits of Eco-Corr®, Eco Film®, Eco Works®; Multi-metal corrosion protection (VpCI); electro-static discharge; designed specifically for electronics; leaves no residue after unwrapping
CorrTainer™ brand of corrugated boxes	Fully recyclable and repulpable; moisture resistant; eliminates the need for secondary packaging in some applications; cost effective, environmentally friendly, corrosion protection; easy to use, with no need for desiccants or poly-coated wraps
EcoShield® Paper and Linerboard	Environmentally friendly barrier coating; Offers the same if not better barrier protection than wax or poly-coated paper; fully recyclable and repulpable; complies with FDA and USDA regulations for direct and indirect food contact; offers protection to both ferrous & nonferrous metals

Ingelheim (Resomer L, Resomer R, Resomer, LR, poly(l-lactide-co-D,l-lactide)) etc., (Nampoothiri *et al.*, 2010). PLA containers have been used for packaging foods such as Biota™ PLA bottled water, Noble™ PLA bottled juices, and Dannon™ yogurts.

Nowadays, many commercial edible coatings are used on fresh and fresh-cut fruits and vegetables. Several commercial products available in the market for postharvest use, such as Biosave (*Pseudomonas syringae*) registered in the USA and “Shemer” (*Metschnikowia fructicola*) registered in Israel (Droby *et al.*, 2009). Pro-long, TAL-Prolong (Courtaulds Group, London), Semperfresh (AgriCoat Industries Ltd., Berkshire, UK), and Natural Shine 9000 (Pace International, Seattle, USA) are commercially available composite coating formulations based on CMC (Nisperos-Carriedo *et al.*, 1992). Nature-Seal (Ecoscience Product System Division, Orlando, FL), is another cellulose-based edible coating formulation used for delayed ripening of tomatoes and mangoes. A commercial fruit coating, Nutri-Save (Nova Chem, Halifax, Canada), was developed to serve as both film former and natural preservative and to create a modified atmosphere around fruits to reduce respiration rate and desiccation of these commodities. The some of the commercial applications of edible coatings on fresh fruits and vegetables have already been discussed (Dhall, 2013). The commercial application of new generation of edible coatings on fresh-cut fruits and vegetables has been discussed (Dhall, 2016).

Conclusion

To date, the majority of the packaging used today is synthetic in nature and has been derived from fossil fuels. However, there are now global concerns about the depletion of non-renewable raw materials for manufacturing plastics. The production of microbial biodegradable polymers from agro-food waste residues seems a promising route to create an innovative, more resilient, and productive waste-based food packaging economy by decoupling the food packaging industry from fossil feed stocks and permitting nutrients to return to the soil (Guillard *et al.*, 2018). Presently, the production of biodegradable packaging is mostly at research level and has limited commercial use. However, growing consumer awareness towards these packages may lead to grow this industry in near future (Rydz *et al.*, 2018). Despite the advantages of biodegradable materials which have been presented by scientists, a number of obstacles in their development potential have to be overcome, such as cost effectiveness, food safety, food quality, improved water vapor permeability barrier and technological application methods. Full commercial production and application of biodegradable packaging is still some way off, but its potential has now being realized.

Bio-Polymeric Packaging Material for Packaging of Raw Food

Sasmita Majhi, Anju Tyagi, and Abhijit Mishra, Indian Institute of Technology Gandhinagar, Gandhinagar, India

Introduction

Food quality preservation and shelf-life extension of packaged foods make packaging a crucial part of food safety (Appendini and Hotchkiss, 2002). Packaging is integral among all food manufacturing processes, since it maintains food quality during processing, storage, transportation, and distribution (Han, 2014; Marsh and Bugusu, 2007a). These processes are responsible for influencing food quality, and consumer health, hence, are related economics of food industry (Han *et al.*, 2018). Petrochemical-based plastics such as polyethylene terephthalate (PET), polystyrene (PS), polyethylene (PE), polyvinylchloride (PVC), polyamide (PA) and polypropylene (PP) have been widely used as packaging materials in food industry for decades because of their large availability, easy processability at relatively low cost, and desirable mechanical (tensile and tear strength), barrier (air and moisture) and thermal insulation (heat sealability) properties (Siracusa *et al.*, 2008; Hu, 2014). However, most of the plastic disposal wastes get accumulated in landfills owing to their slow decomposition and/or resistance to microbial degradation, thus, generating serious problems in the ecosystem (Kirwan *et al.*, 2003). As per a Eurostat report, during 2006–2015, plastic packaging waste amounts to 15.9 million tonnes in Europe, which constitutes nearly 19% of total packaging waste generated by packaging material (EU, 2018). This urges the need for the packaging industry to switch to biodegradable, renewable, as well as cost-effective materials, to reduce burden on the environmental pollution and climate change to certain extent (Siracusa *et al.*, 2008; Petersen *et al.*, 1999).

Development of eco-friendly products using biodegradable materials such as renewable raw materials derived from plant and animal sources have suitable attributes to address these persisting environmental issues (Davis and Song, 2006; Gontard and Guilbert, 1994; Bastioli, 2001). For sustainable growth of food packaging industry, manufacturers are moving towards a “greener packaging” era to address the ecological concerns and consumer demands. To this end, recycled and recyclable packaging materials are emerging as key food packaging trend being an alternate to plastics and other environmentally-unfriendly materials (Del Nobile *et al.*, 2009; Schmid *et al.*, 2012). Biodegradable packaging materials offer advantages over synthetic plastics such as biodegradability and/or compostability, and renewable raw materials (Tharanathan, 2003; Licciardello, 2017; Peelman *et al.*, 2013; Narayanan *et al.*, 2017). Now-a-days both of these properties are of commercial interest in food packaging industry to satisfy market and consumer needs. Biodegradable and recyclable packaging materials include biopolymers and paper-based products (Tang *et al.*, 2012; Kirwan, 2003). These materials can be degraded into simpler substances (water and carbon dioxide) or small molecules upon exposure to open environment (having optimum temperature, moisture, oxygen content and microorganisms) (Siracusa *et al.*, 2008; Davis and Song, 2006). Biodegradable polymers, based on types of raw materials (which could be renewable) have much faster biodegradation rates (varying from weeks to months) compared to petroleum based plastics (extending up to years). Based on the constituents of polymers and available conditions for degradation process, bio-degradation of polymers vary (Siracusa *et al.*, 2008; Gross and Kalra, 2002). Eventually, it minimizes the environmental problems associated with the packaging disposal wastes by reducing the amount of solid-waste in landfills.

Food packaging also includes preservation and protection of food quality during processing, storage, handling and marketing (Coles *et al.*, 2003; Smith *et al.*, 1990). The food packaging industry has developed ways to maintain the food quality (organoleptic properties of food), shelf-life, food safety, and reduce chances of food-borne diseases by reducing effects of oxidation and microbial action on foods (Robertson, 1998). Packaging protects food from environmental impacts such as moisture, gases (O₂, CO₂), heat, light, aroma, pressure, dirt, insects, microorganisms, also provides antimicrobial and antioxidant properties and minimizes any mechanical damage (Brody *et al.*, 2008). Therefore, active food packaging has emerged as a new technology in satisfying consumer and market demands. These are designed to extend food shelf-life by promoting desirable interaction with food by incorporating active substances into packaging aimed to be released/absorbed into food or absorbed/released from the packaged food to the surrounding environment of food (Rooney, 1995; Ozdemir and Floros, 2004). This article discusses biodegradable packaging materials focusing towards its sustainability in accordance to food stability, consumer health and environmental impact.

Properties of Packaging Materials

The protection that needs to be provided by the packaging materials is summarized in Fig. 1.

Properties of the packaging film, including permeability of gases (oxygen and CO₂), water vapor permeability, tensile strength, elasticity, thermal stability, etc., need to be determined for packaging applications. These properties can be modified using different additives such as: cross-linking agents, plasticizers, texture agents, antioxidants, and antimicrobial agents (da Rocha *et al.*, 2018). Standardized protocols are utilized to define barrier properties of different materials used for food packaging.

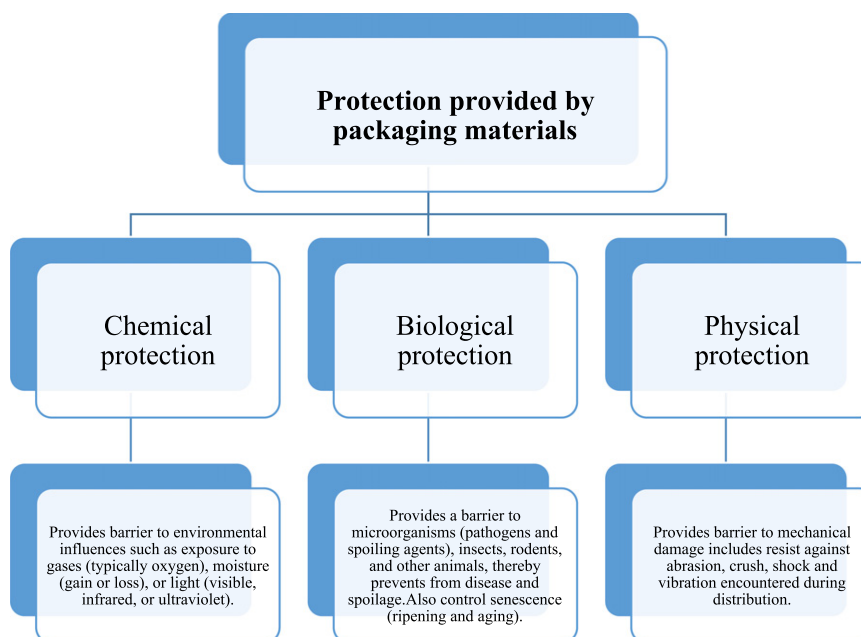

Fig. 1 Summary of protection provided by packaging materials.

Barrier Properties

Oxygen permeability is quantified by the oxygen transmission rate (OTR), defined as the amount of oxygen that permeates per unit area and unit time in packaging materials, measured at different relative humidity following methods recorded in ASTM F1927-07 or ASTM D3985-05. Oxygen barrier property for fresh food packaging (e.g., ready-to-eat meals, fruits, and salads) plays crucial role in its preservation since transfer of oxygen to and from the surroundings through packaging can change food quality and shelf-life.

The water vapor transmission rate (WVTR), defined as the amount of water vapor transmitted per unit area and unit time through packaging materials, measured using different standards such as ASTM E96 (ASTM E96/E96M-16, 2016), ISO 2528 (ISO 2528:2017), TAPPI T 448, and TAPPI T 464. Moisture transfer from the internal or external environment through packaging materials can affect food quality, especially flavor, aroma, color and so on. Thus, OTR and WVTR of packaging films are strongly influenced by nature and composition of the film as well as by the environmental factors (temperature and relative humidity).

Similarly, amount of water absorption by packaging material can be measured by Cobb test (ISO 535), defined as mass of water absorbed on test area over specified time (usually 60s). Grease or oil resistance methods can be determined from stain on paper from greasy substance (TAPPI T 454, and TAPPI T 507).

Mechanical Properties

Mechanical properties of packaging materials are important since they provides protection to the packaged foods by maintaining their integrity during handling and storage.

Mechanical properties of bio-based packaging films include tensile strength, tear propagation resistance, penetration resistance, and seal strength.

Tensile properties

Composition (polymer synthesis, additives, blends, chemical modifications or combinations of above, and also their processing) and storage (temperature condition and relative humidity) conditions of packaging materials can affect their tensile properties. Tensile properties under specified conditions can be measured using standard test method ISO 527-3:1995 (ISO 527-3, 2018) or ASTM D882-12 (ASTM, D882-12, 2012).

Tear propagation resistance

This test ensures packaging is protected against any kind of accidental damages. This evaluates tearing behaviour of film (tear initiation followed by tear propagation) following any localized failure (e.g., initial puncture, rupture due to accidental penetration or impact etc.). Tear propagation of films were evaluated using standard test methods: ISO 6383-2:1983 (ISO 6383-2, 1983) or ASTM D1922-15 (Elmendorf tear method) (ASTM D1922-15, 2015) and ISO 6383-1:2015 (ISO 6383-2, 1983) or ASTM D1938-14 (Trouser tear method) (ASTM D1938-14, 2014).

Penetration resistance

Package integrity might loss due to puncture leading to penetration of contaminants (gases or odors) which can further affect the packaged food quality. This property is usually expressed as load puncture or energy (area under load deformation curve) and can be measured using standard methods: ASTM F1306-90(2008) (ASTM F1306-902008e1, 2008) or EN 14477:2004.

Seal strength

To facilitate sealing and opening of any packaging, a minimum level and an upper limit of seal strength is set. Seal strength is measured according to ASTM F88/F88M-15 (ASTM F88/F88M-09, 2009).

Antimicrobial Activity

Antimicrobial properties of food packaging can delay or inhibit microbial growth responsible for deterioration of food quality leading to off-flavor, discoloration, nutrient loss, and reduced shelf-life, which further enhances chances of food-borne illness (Biji *et al.*, 2015; Malhotra *et al.*, 2015; Cooksey, 2005). Antimicrobial food packaging materials can be developed in two ways: one type packaging is making direct contact with the food and the other type is without making direct contact with the food surface (Sofi *et al.*, 2017; Realini and Marcos, 2014; Kerry *et al.*, 2006). In case of direct contact, antimicrobial agents can be evaporated or migrated (volatile substances) into food products, mostly used for vacuum-packed or wrapped products (Sung *et al.*, 2013). In non-contact antimicrobial packaging, include MAP (modified atmosphere packaging) technologies (Realini and Marcos, 2014), various bioactive compounds, such as: spices, and essential oils, enzymes, polysaccharides, bacteriocins, and other bioactive phytochemicals (Malhotra *et al.*, 2015; Suppakul *et al.*, 2003; Irkin and Esmer, 2015; Raveendran *et al.*, 2018; Hanušová *et al.*, 2013), can be incorporated to produce antimicrobial packaging systems. Incorporation of antimicrobial agents depends on processing techniques (extrusion, compression, or molding) used for preparation of an antimicrobial film as well as on the properties of film material and antimicrobials (heat stability and compatibility) (Lucera *et al.*, 2012).

Antioxidant Activity

Presence of oxygen in food packages facilitate microbial growth, oxidation of nutrients, lipids, and pigments, leading to deterioration of food quality (change in flavor, color, nutritive value, texture). It can form toxic compounds due to degradation of fatty acids, and can also alter the respiration rate and ethylene production of fruits and vegetables leading to their early quality degradation (Gómez-Estaca *et al.*, 2014). So it is necessary to remove oxygen from head space of food packages to maintain food quality and ensure food safety. Though vacuum packaging/MAP in combination with good oxygen barrier in the packaging film can effectively remove oxygen inside packages, residual oxygen during packaging or oxygen permeation due to poor sealing can have effect on the food inside (Coma, 2008; Ahmed *et al.*, 2017).

Oxygen scavengers, containing antioxidant agents, can be added to food packages in different forms (pads, sachets or labels). Oxygen scavengers can be metallic (fine powders of iron and ferrous oxide) and non-metallic (catechol, ascorbate salts, ascorbic acid, sulfites, and enzymes (ethanol oxidase/glucose oxidase)) (Yildirim *et al.*, 2018). Other ways of developing antioxidant packaging is incorporation of antioxidant agents into packaging film itself, where antioxidant compounds are released into food products or head space (Yildirim *et al.*, 2018; Park *et al.*, 2012; De Dicastillo *et al.*, 2011; Shahidi and Zhong, 2005; Torres-Arreola *et al.*, 2007). Release rate of active compounds should be optimized from/into the food packaging. Thus, manufacturing of antioxidant packaging material depends on properties of packaging material and antioxidant compounds. Furthermore, choice of active compound depends on compatibility of food product and active compound. Few examples of synthetic antioxidants include: butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), propyl gallate (PG), tertiary butyl hydroquinone (TBHQ) (Sanches-Silva *et al.*, 2014). To examine antioxidant activity various tests are available, like: radical scavenging assay, ferric-reducing antioxidant power (FRAP), 2,20-azinobis (3-ethylbenzothiazoline-6-sulfonate) (ABTS) assay, 2,2-diphenyl-1-picrylhydrazyl radical (DPPH), N-diethyl-p-phenylenediamine (DPD), and total phenolic content (Abramovič *et al.*, 2017; de Dicastillo *et al.*, 2015).

Bio-Based Raw Materials for Food Packaging Film

The above mentioned properties can be modified using composites, polymers blends, coatings, multilayer systems, chemical treatments, nano-additives or combinations of above technologies to maintain quality and shelf-life of packaged food (Shalini and Singh, 2009; Pawar and Purwar, 2013; Wróblewska-Krepsztul *et al.*, 2018; Johansson *et al.*, 2012). Bio-based packaging materials, along with their composites, developed to meet the needs of sustainable packaging are discussed below.

Biopolymers

Biopolymers based on starch and derivatives

Starch is a polysaccharide produced by plants and is comprised of repeating units of glucose, which includes two types of molecules: amylose (linear and crystalline) and amylopectin (branched and amorphous) (Kaseem *et al.*, 2012). It is mostly extracted from potatoes, corn, wheat, rice, seeds, legumes, cereals, and fruits. Starch-based packaging can be metabolized by microorganisms making them biodegradable.

However, high sensitivity of starch polymers towards water vapor permeability and poor mechanical strength have limited their food packaging application (Rejak *et al.*, 2014; Mali *et al.*, 2005). To overcome these limitations, it is usually plasticized in presence of plasticizers that include glycerol, sorbitol, xylitol or binary polyol mixtures and is extruded or casted to form polymer films (Farahnaky *et al.*, 2013; Sanyang *et al.*, 2015; Talja *et al.*, 2007). Starch is mostly used as a thermoplastic in food industry called thermoplastic starch (TPS) and the type and amount of plasticizer added to them influences their physical, mechanical, thermal and barrier properties (Zuo *et al.*, 2015). For instance, the transition temperature (T_g) decreased slightly with the addition of increased amounts of different plasticizers while the plasticizers increased the water vapor permeability (WVP) of sugar palm starch (SPS) films (Sanyang *et al.*, 2015). Change in WVP values is attributed to plasticizers causing structural modifications in starch network which makes the film matrix less dense but more mobile and flexible (Rodríguez *et al.*, 2006).

TPS still faces multiple issues such as high water susceptibility, poor mechanical properties and low degradation temperatures. To overcome these issues, TPS have been blended with different polymers such as PE, PP, PS, and ABS (Kaseem *et al.*, 2012). PE and PP blends showed improved mechanical properties and thermal stability, PS blends show improved thermal stability but poor mechanical properties, while ABS proved to be incompatible with TPS. Other ingredients have also been blended to starch-polymer matrix to improve their mechanical properties, such as nano-clays, carbon nanotubes (CNT), carboxymethyl cellulose (CMC), microcrystalline cellulose (MC) (Taghizadeh and Favis, 2013; Tongdeesontorn *et al.*, 2011; Chowdhury and Das, 2014).

Biopolymers based on cellulose and derivatives

Cellulose is a linear polymer of repeating glucose units usually found in plant cell walls. A number of cellulose derivatives have been synthesized commercially to extend their applications from food packaging films to water-soluble edible films, since derived celluloses are quite resistant to enzymatic cleavage, microbial attack, moisture and gas permeability, at the same time providing structural and mechanical support (Park *et al.*, 1993; Hefft, 2017). Few of the cellulose derivatives used for food packaging applications are: cellulose ethers (methylcellulose, ethylcellulose, hydroxyethyl methylcellulose, hydroxypropyl methylcellulose, hydroxymethylcellulose, carboxymethylcellulose) and cellulose esters (cellulose acetate, cellulose triacetate, cellulose acetate butyrate) (Siracusa *et al.*, 2008; Turhan and Şahbaz, 2004; Gemili *et al.*, 2009; Sata *et al.*, 2004). Amongst all, Cellulose acetate (CA) is commonly used for food packaging use because of its good barrier properties. CA along with cellulose diacetate (CDA) and cellulose triacetate (CTA) forms rigid wrapping film that is widely used in food packaging application (Paunonen, 2013). Triacetyl glycerol is used as a plasticizer during film molding. Casting composition, wet casting thickness, and drying temperature alter film porosity which further have an impact on the properties of the films (Wu *et al.*, 2014; Suderman *et al.*, 2016). Antimicrobial CA films can be prepared by crystallization of antimicrobial agents like, potassium sorbate, lysozyme, and sodium propionate, within the cellulose films (Gemili *et al.*, 2009; Sayanjali *et al.*, 2011). Therefore, the degree of porosity during drying affects crystallization of these antimicrobial agents. Incorporation of antimicrobial agents in CA films enhances shelf life of packaged food products. Further, keratin filled CA forms compostable films (Paunonen, 2013).

Biopolymers based on proteins

Protein films can prevent food from biological deterioration, microbial growth, control moisture migration and oxidation of nutrients as they offer barrier to vapors, gasses and oils (Yada, 2017). They also functions as carriers of antimicrobials, antioxidants, flavors and colors, which consequently helps to improve shelf-life and safety of packaged products. Few proteins that have been used as edible films include collagen, gelatin, corn zein, wheat gluten, whey protein, soy protein, mung bean protein (Wittaya, 2012).

Collagen is structural protein of connective tissue of bone, tendons, cartilage, and ligaments, in mammals. Collagen films being non-toxic and biocompatible has been successfully used as edible films (Khan and Khan, 2013). Different cross-linking agents such as glutaraldehyde, transglutaminase, and carboxamide, have been used to improve mechanical, and thermal properties of collagen films (Grover *et al.*, 2012). Upon increase in relative humidity collagen films fail to serve as a good oxygen barrier (Aguirre-Loredo *et al.*, 2016). However, this low resistance of collagen hydrosylates to moisture can be improved by enhancing the cross-linking density with polysaccharide derivatives (Lin and Gu, 2015; Tierney *et al.*, 2009). Collagen and synthetic polymers (PVA, PVP, and PEG) have been blended and casted to form films that possess high tensile strength (Vesely *et al.*, 2015; Sionkowska, 2012).

Gelatin is a natural water soluble protein obtained from the partial hydrolysis of collagen. Active packaging to preserve and improve food shelf-life includes films and coatings having natural additives that comprise essential oils or extracts obtained from plants and spices which exhibit antimicrobial and antioxidant properties (Clarke *et al.*, 2016). Few examples of such active additives are cinnamon essential oil, tea polyphenols, peppermint essential oil, orange leaf essential oil, bacteriocins, beet root residue powder, and thyme essential oil (Ramos *et al.*, 2016). These natural additives are able to reduce food deterioration by preventing food oxidation or microbiological effects on them. Also to enhance structural features of gelatin based films, different substances such as plasticizers, cross-linkers, and strengthening agents were added to reduce hygroscopic nature of gelatin by modifying their hydrophilic character or forming strong covalent bonds in the

protein-film network (Grover *et al.*, 2012; Suderman *et al.*, 2018; Catalina *et al.*, 2011; Rawdkuen *et al.*, 2012). Different biopolymers have been blended with gelatin to improve their mechanical and water resistant properties such as starch, chitosan, pectin, whey protein, lignin, or isolates of fish protein etc. (Al-Hassan and Norziah, 2012; Mohammed Manshor *et al.*, 2018; Bai *et al.*, 2013; Jiang *et al.*, 2010). Biodegradable gelatin based films have also been produced using water soluble synthetic polymer like: PVA (Dafader *et al.*, 2016).

Plant proteins, namely zein (protein found in corn), are relatively hydrophobic due to high amount of non-polar amino acids. Zein shows good film-forming ability and solubility in ethanol; forms mostly hydrophobic and hydrogen bonds within chains of film-matrix (Yamada *et al.*, 1995). Zein film exhibits good water vapor permeability (Wang and Padua, 2004) and addition of suitable plasticizers enhances their flexibility (Paramawati *et al.*, 2001). Flexible antimicrobial and antioxidant food packaging have been developed using zein/polymer or fatty-acid blends viz. PP/zein and zein/wax incorporating suitable antimicrobials and/or antioxidants (Arcan and Yemenicioğlu, 2013; Yemenicioğlu, 2016).

Wheat gluten, another commonly used plant protein, has good film-forming properties because of its integral cohesive and elastic nature (Gueguen and Popineau, 1998). Wheat gluten is insoluble in water, but shows solubility in aqueous solutions having varying pH (Tanada-Palmu and Grosso, 2003). It contains glutenins (offers stronger films and better barrier properties) and gliadins (offers good optical properties) (Kuktaite *et al.*, 2011). Gluten films have low oxygen permeability but high water vapor permeability because of hydrophilic nature of its protein. Addition of film plasticizers such as, glycerol can improve flexibility, tensile strength, oxygen and water vapor permeability (Gontard *et al.*, 1993).

Poly(lactic acid)(PLA)

PLA is a biodegradable bioplastic, that has been extensively used as suitable replacement of non-degradable petrochemical-based plastics (Muller *et al.*, 2017). Due to its wide availability, desirable mechanical properties, easy processability, and low comparative cost, PLA and PLA/starch blend products have the largest market share in biodegradable plastic market. PLA-based films are brittle in nature, therefore, different plasticizers (Tanrattanakul and Bunkaew, 2014; Jamshidian *et al.*, 2013; Mekonnen *et al.*, 2013) such as: glycerol, tributyl acetyl citrate (TBAC), glycerol triacetate (GTA), tributyl citrate (TBC), triethyl-2-acetyl citrate (TEAC), PEG of different MWs, and epoxidized soybean oil are added to alter their mechanical properties by decreasing the glass-transition temperature (T_g) and increasing strain at break (Arias *et al.*, 2013). Turalija *et al.* modified surfaces of PLA films with silver by simultaneous plasma polymerization/sputtering to achieve antimicrobial PLA films (Turalija *et al.*, 2016). Oxygen permeability of PLA films can be improved by addition of chitosan and montmorillonite (MMT) clay (Muller *et al.*, 2017). PLA can, possibly, be a good carrier for antioxidants like butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), tert-butylhydroquinone (TBHQ) and ascorbyl palmitate, and control food oxidation reactions (Jamshidian *et al.*, 2012; Byun *et al.*, 2010). Factors affecting antioxidant release from PLA include simulant polarity, film thickness, temperature, antioxidant solubility in simulant, polymer degradation, and antioxidant molecular weight (Jamshidian *et al.*, 2013). PLA/chitosan blend films have showed significant antimicrobial activity (against aerobic mesophilic and coliform microorganisms) with less rigid and stretchable films (Bonilla *et al.*, 2013). Corona treated (CT) PLA films have showed improved gas (O_2 , CO_2 , He,) barrier properties (Rocca-Smith *et al.*, 2016). Despite these advances, PLA and PLA-blended film properties still need to be improved, especially their barrier properties (moisture and gas), mechanical properties, and thermal stability.

Polyhydroxyalkanoates (PHAs)

PHAs are biodegradable natural plastics produced by microbial fermentation of carbon-based feedstocks such as: corn starch-based glucose, cane sucrose (Koller, 2014) or sugar beet sucrose under nutrient-limited conditions. PHAs can act as substitute to polystyrene (PS), polyethyleneterephthalate (PET), low-density polyethylene (LDPE) and high-density polyethylene (HDPE). PHA films are processed using injection molding (Peelman *et al.*, 2013), melt-extrusion techniques (Thellen *et al.*, 2008), and thermoforming. Thermal stability and mechanical properties of PLA films can be improved upon incorporation of kaolinite nanofillers (Peelman *et al.*, 2013). Oxygen permeability of PLA was reduced up to 90% after addition of 5 wt% cellulose nanowhiskers (CNW) (Peelman *et al.*, 2013). Addition of montmorillonite-layered silicate, coating of PLA-Si/SiO_x, or thin AlO_x-coating, to PLA improved the barrier properties (water vapor and oxygen) of PLA films making it applicable for food packaging especially for medium shelf-life products (vegetables, processed and/or fresh meat, cheese) (Peelman *et al.*, 2013). Hany *et al.* demonstrated anti-biofouling properties of medium chain length PHA (mcl-PHA) by conjugation of zosteric acid (Koller, 2014). PHA-based composites have improved film barrier properties, thermal stability, and mechanical properties, making them good candidates to be used as food packaging material.

Paper and Paper-Board

Paper and paperboard are made of an interlaced network of cellulose fibers, obtained from trees and/or recycled from recovered papers. Additives are added to pulp, during processing or after processing, to attain different technical functionalities of paper and board required for food packaging purpose (see "Relevant Websites section") (Kirwan, 2003; Delphine *et al.*, 2004). Application of paper and board in packaging have been enhanced in last 50 years because of their many advantages such as: recyclability (as prepared from renewable raw materials, recovered paper), biodegradability, robustness and adaptability, low cost of production, and ease of being molded, coated and printed (Delphine *et al.*, 2004). Global paper packaging market was valued USD 64.4 billion in 2017 and is expected to reach USD 82.4 billion by 2023 (see "Relevant Websites section") Types of papers used for food packaging are as follows (Kirwan, 2003): Kraft paper, used for paper bags in grocery store, wrapping, cushioning and other

uses; Sulfite paper, used as bags and wrappers for bread rolls, cakes, savory products and biscuits; Greaseproof paper, used to wrap fresh fish/meat, oily foods, also used as liner for biscuits, butter/cheese, snack foods; Glassine, used as liner for fast foods, baked foods, biscuits; Parchment paper, used for butter, cheese, margarine packaging; Laminated paper (paper laminated with aluminum/plastic to improve its properties) used for packaging of dried products (herbs, and spices, soups).

Paperboards are mainly used to make containers (cartons, boxes, trays) for shipping (Marsh and Bugusu, 2007b). Types of paperboards include: White board (typically used as the inner layer of a carton for direct contact with food); Solid board (used as baking trays, pizza boxes, trays for fruits and vegetables, clamshell packaging, also used as liquid cartons after lamination with PE); Chipboard (used as outer layers of cartons for foods like: cereals and tea); Fiberboard (used for shipping bulk food and retail food products).

In spite of their wide usage, there remains a need to improve the strength of paper material, enhance their barrier properties to maintain functionalities, make them resistant to moisture, and reduce quantity of raw materials used for manufacturing paper and board based packaging material. Ways of improving the barrier properties of paper based packaging is being widely studied. A few bio-materials have been investigated as barrier coatings (focusing mainly on oxygen, water vapor, and aroma permeability) for paper such as starch, corn, chitosan, alginate, cellulose derivatives, whey proteins, soy proteins, caseinates, wheat gluten, and zein (Khwaldia *et al.*, 2010; Lin *et al.*, 2017; Wang and Jing, 2016; Vikele *et al.*, 2017; Kopacic *et al.*, 2018; Jiang *et al.*, 2014; Elyas *et al.*, 2016; Xu *et al.*, 2016; Mazhari Mousavi *et al.*, 2018; Han and Krochta, 2001; Khwaldia *et al.*, 2014; Guillaume *et al.*, 2013, 2010; Trezza and Vergano, 1994; Parris *et al.*, 2002). High amount ($> 10 \text{ g/m}^2$) of whey protein coating on paper reduces water vapor permeability of paper and also acts as a grease barrier (Han and Krochta, 2001). Further, addition of sucrose to less concentrated whey protein coatings imparted good grease resistance to paper. A composite coating of sodium caseinate/wax on paper improved water vapor barrier property of paper (Khwaldia, 2010; Rastogi and Samyn, 2015). Wheat gluten-coated paper showed an decrease of nearly 56% in WVTR and 400-fold reduction in oil wettability in comparison to uncoated paper (Guillaume *et al.*, 2010; Cho *et al.*, 2012). Soy protein-coated paper also showed improvements in the oil barrier properties (Park *et al.*, 2000). Adequate weight of zein coatings on paper was found to decreased WVTR and improve grease resistance (Khwaldia *et al.*, 2010). Chitosan coating to paper decreased WVTR by up to 62.5% when compared to normal paper (Bordenave *et al.*, 2007). Paper impregnated with starch acetate showed improvement in water vapor permeability due to reduction in diffusivity (starch impregnation reduces pores available for water vapor exchange) and solubility (starch less hygroscopic than paper) (Larotonda *et al.*, 2005; Fringant *et al.*, 1998; Ni *et al.*, 2018). Alginate in combination with chitosan coating enhanced fat barrier properties paper (Khwaldia *et al.*, 2010; Ham-Pichavant *et al.*, 2005). Paper coated with carboxymethylated nano-fibrillated cellulose showed 6-fold decrease in air permeability and increase in grease resistance (Xu *et al.*, 2016; Syverud and Stenius, 2009; Aulin *et al.*, 2010).

Concluding Remarks

The current trend of sustainable food packaging is based on use of renewable and recyclable materials, reduction in consumption of raw materials (reducing demand on fossil fuels), and reduction of waste, which have increased the interest in biodegradable food packaging. Improved properties, functionality, and lower cost options will undoubtedly enhance acceptance of bio-degradable packaging in current market. Still few short-comings need to be addressed before we observe a major shift of food packaging to bio-based materials that satisfy consumer demands and environmental safety. Researchers and scientists are working towards this aspect trying to expand bio-based food packaging industry in most sustainable way using biopolymers and their composites.

Introduction

Geological formations or reservoirs of oil and gas where CO₂ can be injected and stored for a long time include deep saline formations, depleted oil and gas fields, and unmineable coal seams. Each of these formations has a distinct capacity for holding and trapping CO₂, and each method of geologic storage has different cost components and projections. The storage of CO₂ can occur in a variety of geologic formations chosen for their ability to efficiently trap CO₂, the capacity of the formation to accept the intended volume of CO₂, and the formation's ability to limit the extent to which it migrates throughout the structure [1]. Oil and gas field reservoirs are the porous rock matrix that once held oil/gas. Injected CO₂ may trap into this porous and impermeable rock matrix. Moreover, during the long-term storage, CO₂ injected into these oil/gas reservoirs helps in recovering trapped oil reserves that are difficult to reach [2,3]. The deep saline aquifer consists of porous rock saturated with brine with a cap of impermeable rock formations to serve as the trapping mechanism for the CO₂ once it is injected. These types of formations have higher storage capacity and are more widespread regarding their location in comparison to oil and gas reservoirs and coal seams [4].

Once the fossil fuels from depleted reservoirs have been removed, CO₂ can be injected into the layer of porous rock where the clay particles and sediment grains packed the cap rock too densely for the CO₂ gas to move through it. Thus the injected CO₂ is permanently trapped in these fields.

For the existing reservoirs, CO₂ is widely used in oil recovery utilizing an enhanced oil recovery approach. Primary production of oil by its natural pressure could only produce about 5%–20%, and after this approach comes the secondary recovery stage in which water is incorporated to extricate the immobile and trapped oil [1,5,6]. Still, after secondary recovery completion, at least 50% of the original oil in place (OOIP) remains captive in the oil reservoir [7–11]. A CO₂ injection can dislodge more oil by displacing and dissolving trapped oil [12,13]. A number of CO₂ flooding projects are in practice or have been accomplished worldwide, which recover thousands of barrels of oil every day. In addition to oil recovery by means of CO₂, the process is equally useful for CO₂ long-term storage in oil reservoirs. The CO₂ as greenhouse gas emission is well thought out as the most crucial factor in global climate change. CO₂ flooding potential would be much more if at low cost and a substantial volume of the CO₂ gas is available.

EOR using CO₂ as an injected material offers a pathway to store large volumes of CO₂ and oil production boosting process to offset capture facility capital costs. Furthermore, after the EOR operations accomplishment, the sequestration activities may linger to maximize storage of CO₂ in the depleted reservoir [14].

Here we discussed the potential of CO₂ to use as EOR injection phase to boost the crude oil production while at the same time storing CO₂ gas permanently under the subsurface.

CO₂ EOR Potential

Approximately 1 kg of injected CO₂ can recover one-quarter extra oil. The produced carbon dioxide when oil is burnt, in most of the projects, is disposed of and wasted to the environment. At high pressure, CO₂ mixes with the oil and can recover up to 40% of the remaining oil (after water flooding). From the literature and case studies in the USA, approximately half of the country's water flooded oil fields could be exploited beneficially by CO₂ flooding. Light crude oil fields are considered as the preeminent option for CO₂ flooding process, as the larger North Sea fields are an attractive prospect of CO₂ injection compared to American fields [15].

Yanchang Petroleum Group in China is implementing CO₂ capture coupled with EOR in Ordos Basin, which is considered as one of the leading areas of CO₂ emission in China. Extensive R&D was done to check geological conditions suitable for the CO₂-EOR process. It was found that more than 87% of Yanchang oil reservoirs in Ordos Basin, China are good for the CO₂-EOR approach with tremendous CO₂ gas storage capacity [16].

Nicholas *et al.* analyzed the database of more than 30 CO₂-EOR projects to better understand the process of CO₂ retention in the reservoir, its oil recovery performance, and the CO₂ utilization in net for EOR process. At three of the selected sites, they calculated the cumulative CO₂ retention and found 23.1%, 48.3%, and 61.8% were retained. The incremental oil recoveries for these sites were 5.3%, 12.2%, and 21.5% of the OOIP (original oil in place) of the reservoir, and the net CO₂ utilization was calculated to be 4.8, 8.7, and 10.5 Mscf/STB (stock-tank barrel). The work provides useful information to estimate the potential range of expected performance of CO₂ injection, and CO₂ storage potential in the candidate fields [16].

CO₂ Storage and EOR Working Mechanism

Literature indicated that around 40%–50% volume of the injected CO₂ gas is stored enduringly in the porous medium. Primarily, it is the residual and solubility trappings' mechanisms that govern the CO₂ storage process. A CO₂ gas injection at immiscible

Fig. 1 Temperature and pressure effect on CO₂ flooding.

settings (i.e., $Pop < MMP$) favors higher volume of CO₂ loading in the porous medium. CO₂ storage is optimal near operating pressures at close to the minimum miscibility pressure (MMP) of the system and beyond that operating pressure; the storage capacity of CO₂ is not significantly improved. On the other hand, conferring to the EOR point of view, recovery factor is considerably boosted by increasing pressure and attain maximum value at the miscible operating pressure condition (i.e., $Pop \geq MMP$) [17].

The CO₂-EOR oil recovery performance depends on the oil reservoir temperature, pressure, and the crude oil composition. On the basis of mode of action of CO₂ used in EOR under the particular set of reservoir conditions, the basic mechanism of the CO₂ performance can be broadly divided into five different regions as shown in Fig. 1 [18].

In region I, the CO₂ solubility in the crude oil is the controlling parameter of CO₂ oil recovery performance. Under these reservoir conditions, shown in region I of Fig. 1, the CO₂ gets dissolved when it contacts with the reservoir crude oil. The dissolved CO₂ swells the oil; due to this swelling of oil, it forced the oil-water to come out of the pores of the rock. This process leads to the saturation of the crude oil in pores and increases its relative permeability, which favors flow conditions of the oil trapped in the pores. The viscosity of the crude oil in the reservoir is drastically decreased by the CO₂ saturation in the crude oil, which ultimately accelerates the oil drive towards the production wells.

In region II at an intermediate pressure and high temperature conditions, (in addition to the oil swelling and its viscosity reduction as in region 1 occurs typically), the process of CO₂-EOR is dependent on the oil droplet swollen; the light hydrocarbon of the crude oil vaporization takes place.

In region III, CO₂ action mechanism is similar to region II. It involves the swelling of oil and reduction in viscosity factors as in region II as the driving forces to recover the trapped oil at the same pressure conditions as in region II but at lower temperature settings. The CO₂-rich phase formed by the CO₂-rich liquid front formation due to the lighter crude oil components extraction process, it further contacts the oil and even lighter components are extracted. This process ultimately leads this fluid to develop the miscible conditions with the oil. This process is termed the multiple contact miscibility.

In region IV, a high-pressure mechanism exists. Oil swells in this set of conditions, which reduces its viscosity as in the other regions. However, the process of vaporization and its miscibility by multiple contacts happens in a very quick manner. Therefore, the process is considered as "first contact" miscible with crude oil of the reservoir. The CO₂ rich oil phase and oil-rich CO₂ phase become indistinguishable as they are present in one phase.

These mechanisms are the mode of actions of CO₂ in a reservoir for the productive and effective uses of CO₂ for oil recovery applications.

The CO₂-EOR oil recovery process can be classified as miscible and immiscible processes for the oil displacement [17]. The CO₂ miscible and immiscible processes take place under specific conditions of pressure, temperature, and the oil composition. As discussed earlier, the CO₂ is immiscible with oil on its first contact with oil. However, as it makes contact with crude oil of the reservoir, it is enriched with light components present in the crude oil. This composition modification develops a miscible zone between the oil and CO₂. The process works more efficiently above MMP. Fig. 2 shows the mode of action of CO₂-EOR process [19].

In contrast to miscible process, the immiscible process of oil displacement is in action where the pressure of reservoir is less than the MMP or in case the composition of the crude oil is not favoring miscibility with the CO₂. In these circumstances, the oil swelling, oil viscosity reduction, and also lowering of the surface tension are the dominant and primary modes of action of CO₂ oil recovery process.

Fig. 2 A schematic of the water-CO₂ EOR operation.

Both miscible and immiscible injection approaches are contributed to the oil recovery by two different mechanisms, that is, oil swelling and interfacial tension reduction process. However, extraction of light components in the miscible injection scenario is considered as the core mechanism of the oil recovery process [17].

Problems of CO₂-EOR

Theoretically as well as practically at the small scale in core lab tests, nearly all of the trapped quantity of the oil can be recovered by using the CO₂-EOR strategy, mainly when the CO₂ injection occurs above the MMP. However, some properties of CO₂ such as the low viscosity and density, and the high CO₂ mobility, affect the overall performance severely and results in a poor oil sweep efficiency of the process [20,21]. Schematics of the CO₂ viscous fingering and gravity overriding processes are shown in Figs. 3 and 4, respectively [7,19].

High mobility and low viscosity result in CO₂ viscous fingering and early breakthrough, hence CO₂ passes ahead of the native reservoir fluids [22–24]. The low density of CO₂ compared to the oil triggered gravity override and inhibits the CO₂ contact with oil in the lower regions of the reservoirs. CO₂–oil is segregated from each other and CO₂ occupies the attic and oil remains at the reservoir cellar [25,26]. Figs. 3 and 4 explain the CO₂ problems that commonly occur in a reservoir.

Solutions to Overcome CO₂ Problems

The increase in CO₂ density is not feasible in practical terms. Conversely, substantial control of the CO₂ mobility is possible via different tactics such as water alternating gas (WAG) method. This technique is the easiest (but not very effective) way to overcome the mobility issues of the injected gas. In this practice, the CO₂ saturation is reduced by alternate slugs and as a result, reduces the relative permeability as well as the CO₂ mobility. However, this exercise of using alternate water and gas slugs may obstruct the CO₂ and oil mixing. The process also delays the injection of the specific amount of CO₂. Additionally, facilities for water flooding are also required. The WAG practice deepens the problems of oil and water separation related to the postproduction, and the production of water is also increased. Hence, the scientific community's attention has been focused towards other techniques as well to minimize the CO₂ mobility issues. The use of CO₂ thickener in a small amount to increase the CO₂ viscosity is another attractive and effective option to control the CO₂ mobility. Though direct thickeners used as CO₂ viscofiers similar fluorothickeners formed at the University of Pittsburgh have been developed, these are only available at lab scale, and their commercial availability is uncertain [27–29].

Foam to Overcome CO₂ Mobility Issues

CO₂ mobility reduction using foam flooding is another approach to resolve the CO₂ gas mobility concerns. The scheme involves the injection of alternate CO₂ and the surfactant slugs. In this process, the foam generated inside the porous media exhibits an incredible CO₂ mobility reduction [30–33]. Fig. 5 explains the foaming action in a reservoir [34].

Fig. 5 illustrates that the CO₂ gas alone cannot sweep the oil reservoir adequately. The WAG practice is comparatively better, but unswept zones are still present. In this situation, foam alternate WAG may exhibit the improved sweep performance. Foam slows down the CO₂ breakthrough as well as it also reduces gas cap gas production. CO₂ gas mobility reduction is a key

Fig. 3 Schematic of the CO₂ viscous fingering.

Fig. 4 CO₂ gravity override and early breakthrough (schematic).

advantage of the foam usage. Of course, the stability of the foam will influence the efficacy of the injection of foam in the reservoir [35–37]. Fig. 6 shows the process and explains how foam helps to overcome CO₂ fingering and slows down early breakthrough [38,39].

CO₂ Sequestration in Existing EOR Sites: Potential and Benefits

The innovation and improvement in carbon capture technology pooled with CO₂-EOR hold the potential to reduce the carbon footprint released from coal-fired power plants as well as from the other sources. At the same time, the approach is equally good and contributing significantly to crude oil recovery. Historically, injection of CO₂ in a reservoir or deep formations is very old. CO₂-EOR started in the 1970s at SACROC field in West Texas to recover oil. The properties of crude oil changed as the CO₂ mixes with it, which results in producing additional trapped oil flowing towards the production wells.

CO₂ EOR approach is much mature in the world, especially in the United States. However, many of the target reservoirs still have not been flooded with CO₂. As oil is more viscous than CO₂, first its viscosity is reduced, and a mixture of oil and carbon dioxide (CO₂) is brought to the surface. Currently, around 22 companies are working on about 99 different projects using EOR-CO₂ approach for oil production.

Many of the reservoirs running at EOR stage may be ideally good for CO₂ sequestration as these sites:

- (1) Provide traps which hold oil over geologic time,
- (2) Have CO₂ gas injection and transportation infrastructure,
- (3) May offer potential for additional stacked storage,

Fig. 5 Explanation of foaming action in reservoir.

Fig. 6 Foam action to overcome CO₂ fingering and slow down early breakthrough.

- (4) Offer commercial benefits for CO₂ capturing companies,
- (5) Have already proven the injectivity of the reservoir,
- (6) Facilitate underground CO₂ gas management,
- (7) Present where the general public accepts these injection projects, and
- (8) These sites also have advantages of monitoring, already available infrastructure, experienced service providing company is in contract, and lastly, have preinjection data, etc. [14–17]. Even with these advantages, for long-term CO₂ containment for atmospheric purposes as well as for reduction in CO₂ quantities, these practices may ensure better prospects for CO₂ capture and its sequestration. Long-term storage of CO₂ can be improved by validating the reservoir and the suitability of its existing wells. Secondly, the storage capacity may be enhanced by evaluating the compatibility of well construction with long-term exposure to low pH fluids. At the third step, calculating CO₂ volume that can be stored permanently. Finally, by calculating the longevity of the CO₂ in the reservoir, this may be performed by flood monitoring or by monitoring and site closure [14–17].

Conclusions

Enhanced oil recovery using CO₂ offers a channel to store vast volumes of CO₂ permanently under the subsurface in depleted crude oil reservoirs. This CO₂-EOR strategy can be a reliable approach to recover trapped oil from the reservoirs as well as to permanently store the excess of CO₂ to make the environment clean. Almost 40%–50% of injected CO₂ quantity can be stored forever in the porous medium. It is also concluded that the foam can be effectively used to overcome the problems associated with CO₂ gas injection, which include but are not limited to the low viscosity and density of CO₂, and the high CO₂ mobility, which normally result in a poor oil sweep efficiency of the enhanced oil recovery process. Utilizing CO₂ for enhanced oil recovery is a well-understood technique, and it is also being practiced commercially. CO₂, on the other hand, in the context of greenhouse gases, needs to be sequestered and stored deep in the earth to reduce its adverse impacts to the environment. It is evident that using CO₂ for EOR not only can help to produce trapped oil to meet energy demands, but also can assist in permanent storage of CO₂ gas in deep reservoirs. It is also concluded that using novel ways of conducting CO₂-EOR process could help a lot to achieve an all-win solution both for the oil business and help to achieve climate change mitigation goals. In nutshell, it is concluded that moving from a simple EOR technology to “EOR + ” technology, represents a huge potential, attractive, and economically favorable technology. CO₂-EOR strategy can be modified such as by use of foam, CO₂ philic surfactant to play a much significant role in oil recovery and to improve the capacity for CO₂ storage. Overall this CO₂-EOR + technology can be used both for CO₂ long-term storage in addition to oil recovery in such a manner that is economically remarkable for industry.

Introduction

Applications to environmentally friendly natural materials for industrial products has attracted attention in the industrial fields along with the recent rise in environmental consciousness. As an example, natural fiber reinforced plastics using natural fibers as reinforcing materials are used as interior materials for automobiles (Holbery and Houston, 2006). On the other hand, natural fiber reinforced biodegradable resin matrix composite materials, which is called green-composites, are beginning to be used for enclosures of electronic devices and spare tire covers of automobiles (Netravali and Chabba, 2003; Sujito and Takagi, 2011; Takagi and Takeichi, 2012). Therefore, it can be said that the application of these natural fibers to industrial products is entering the practical stage. From a different viewpoint, in the musical instrument industry, there is a demand of manufacturers to recycle waste materials generated after manufacturing the instruments, as well as user needs to use sustainable renewable instruments using natural materials even if their cost is high. However, among woods used as materials for musical instruments, there are many things that have become rare resources now. For example, rosewood used for marimba, silophone, etc., is said to take over 200 years to grow sufficiently as a material. Moreover, it is said that strict growth control is required. Therefore, substitute materials using glass fiber reinforced plastics etc., are currently being developed (Abe, 1999; Miyakosi *et al.*, 2000). However, a substitute material of 100% natural material has not been developed yet. Therefore, in this research, we aim to develop sustainable materials, which is important not only to environmentally friendly but also to resource-recycling rare timber (the soundboard wood has a higher Young's modulus and a lower attenuation rate than other woods) (Ono, 1996). In previous research, we focused on bamboo growing more rapidly, requiring only about 30 days to grow sufficiently, and widely in Japan as unused forest resources and we proposed a method to extract high quality bamboo fibers using a machining center to improve the shape accuracy of fibers extracted (Ogawa *et al.*, 2008). Next, we proposed a sustainable manufacturing system focusing on the natural growth of bamboo and evaluated environmental impact by LCA (Ogawa *et al.*, 2010). Moreover, we fabricated self-adhesive molded bodies of 100% bamboo fiber, which is an isotropic and homogeneous material were produced by a hot press method. As molding conditions, first, only the molding temperature was changed to evaluate the properties of the molded specimen, and it was revealed that an appropriate temperature exists (Ogawa *et al.*, 2010). However, the influence of other molding conditions including the shape of the fiber has not been evaluated. Therefore, in the present study, we aimed to clarify the influence of molding condition factors on the properties of molded bodies by preparing molded bodies under various molding conditions other than molding temperature and evaluating their mechanical properties.

Experimental Methods

Extraction of Bamboo Fiber and Hot Press Forming of Products

Natural bamboo with density of 0.7-g/cm^3 was air dried and used as a test material. We cut the straight culm (bamboo straight and branch free) of bamboo with an outer diameter of about 50-mm into a cylindrical shape and fixed it in the machine table of a 3-axis vertical machining center. Bamboo fiber was extracted by processing with a spiral tool path shown in Fig. 1. In order to extract bamboo fiber with straightness, a ϕ 6-mm straight end mill with straight two flutes, which is made of high-speed steel, was used as a cutting tool. Cutting conditions were fixed at a tool rotation speed of $10,000\text{-min}^{-1}$, a feed speed of 1000-mm/min , and a radial depth of cut of 0.05-mm . Bamboo fibers of different lengths were extracted by changing the axial depth of cut ($\approx$ fiber length), but base value was 10-mm .

A self-adhesive bamboo fiber board was produced by performing hot press molding only with the bamboo fiber obtained in this way. The shape of the bamboo fiber board was a rectangular parallelepiped of $25\text{-mm} \times 125\text{-mm} \times$ various thickness, and bamboo fibers were randomly oriented and formed. The hot press forming conditions were as follows: standard weight of 7.0-g , molding pressure of 20-MPa , molding time of 10-min , molding temperature of 190°C (Ogawa *et al.*, 2010) as standard conditions shown in Table 1. In the present study, the influence of these on the bamboo fiber board properties was evaluated with the bamboo fiber amount M , the mixing ratio ϕ of the bamboo powder, the fiber length L , and the molding pressure P as molding condition factors.

Table 1 Standard condition of hot press forming for fabrication of self-adhesive bamboo fiber board

Hot press forming temperature T ($^{\circ}\text{C}$)	190
Hot press forming pressure P (MPa)	20
Hot press forming time T_h (min)	10
Cooling time T_c (min)	30
Weight of bamboo fiber M (g)	7
Length of bamboo fiber L (mm)	10
Rate of bamboo powder ϕ (%)	0

Evaluation of Performance of Product Made From Bamboo Fibers

Static characteristics such as bulk density, bending strength and Young's modulus were evaluated on the assumption of application to automotive interior materials and spare tire covers. We also evaluated dynamic characteristics such as natural frequency and logarithmic damping factor, assuming application to musical instrument materials.

For the density, the bulk density before molding was determined from the volume and mass of the container, and the bulk density after molding was obtained from the size and mass of the molding. The bending strength and Young's modulus were measured by a three-point bending test (loading speed 5-mm/min, distance between gauge points 80-mm) using a universal tensile testing machine.

The natural frequency and the logarithmic damping rate were obtained by fixing one end in the longitudinal direction so that the bamboo fiber board becomes a cantilever beam. We applied an external force near the free end of the other end to vibrate so that the time history of the displacement was measured with an eddy current type displacement sensor. At this time, a conductor sheet with a thickness of 20- μm was attached to the surface of the bamboo fiber board. The primary natural frequency and the logarithmic damping factor were determined the measured value. Hereinafter, the natural frequency means the primary natural frequency.

Experimental Results and Discussion

Influence of Board Thickness

Since self-adhesion between bamboo fibers was considered to be due to thermal fusion of components contained in bamboo fiber, in the previous study (Oawa *et al.*, 2010). Therefore, as molding conditions, firstly only the molding temperature was changed to evaluate various properties of the bamboo fiber board. As a result, it was revealed that an appropriate temperature exists. If the properties of the bamboo fiber board are attributable to thermal fusion of the fibers, it is considered that the thermal conductivity to the inside of the bamboo fiber board changes. That is, the characteristics of the bamboo fiber board also can change when the thickness t changes. Therefore, by changing only the fiber weight M used for the bamboo fiber board, molded bodies having different thicknesses were produced, and the influence of the plate thickness on the bamboo fiber board characteristics was investigated.

The appearance of the bamboo fiber board is shown in Fig. 2. As the plate thickness increases, the area of the brown part (black part) on the surface of the molded article tends to decrease. This browning phenomenon is called a Maillard reaction. It is a phenomenon accompanying heat softening of hemicellulose which is one kind of sugar contained in bamboo fiber. Since the area of the brown part due to this reaction tends to decrease as the plate thickness increases. There is a concern that when the plate thickness is large, the interior is not sufficiently heated. Changes in the bulk density of the bamboo fiber board with plate thickness

Fig. 2 Appearance images of self-adhesive bamboo fiberboard by changing board thickness ($\phi=0\%$, $L=10$ mm, $P=20$ MPa).

Fig. 3 Effect of board thickness on bulk density of self-adhesive bamboo fiberboard ($\phi=0\%$, $L=10$ mm, $P=20$ MPa).

are shown in **Fig. 3**. It is found that the bulk density of the bamboo fiber board gradually increases as the plate thickness increases. This is presumably because the heat conduction to the inside of the bamboo fiber board became insufficient as the plate thickness became larger, and moisture contained in the bamboo fiber remained unvaporized.

Changes in Young's modulus and bending strength of the bamboo fiber board with plate thickness are shown in **Fig. 4**. It is found that when the plate thickness is increased, the Young's modulus of the bamboo fiber board gradually decreases, and the bending strength becomes maximum when the plate thickness is about 2-mm. **Fig. 5** shows SEM images of the fracture surface of the bamboo fiber board when the thickness is 1.7-mm. Many cavities (voids) are generated inside the bamboo fiber board, and this cavity is thought to reduce thermal conductivity to the inside of the bamboo fiber board. Under the same molding condition, the volume ratio of this cavity to the bamboo fiber board is considered to be proportional to the plate thickness. Therefore, as the thickness increases, the thermal conductivity of the cavity is further lowered due to the cavity. From this fact, it is considered that the reason why the bending strength decreases when the plate thickness is as large as 5.6-mm is due to insufficient thermal fusion bonding between the fibers due to insufficient heat conduction to the inside of the bamboo fiber board during molding. On the other hand, the reason why the bending strength became small even when the plate thickness is 1.0-mm is believed to be because the bamboo fiber undergoes thermal damage due to overheating and the strength of the fiber itself is reduced. Even in the previous report, when the molding temperature was 220°C, which was formed at a high temperature, embrittlement of the fiber due to carbonization occurred and the strength of the bamboo fiber board was lowered.

Measurement results of natural frequency and logarithmic decay rate with plate thickness are shown in **Fig. 6**. As the plate thickness increases, the natural frequency increases and the logarithmic attenuation factor also increases. Here, the natural frequency f_n of the bending vibration of the cantilever and the logarithmic attenuation factor $\tan\delta$ are expressed by Eqs. (1) and (2), respectively. The result of calculating the natural frequency and the logarithmic decay rate using the values obtained in the experiment is also shown in **Fig. 6**.

$$f_n = \frac{\lambda^2}{2\pi l^2} \sqrt{\frac{EI}{\rho A}} = \frac{\lambda^2}{2\pi l^2} \sqrt{\frac{Et^2}{12\rho}} \quad (1)$$

$$\tan\delta = \frac{4.4\pi}{T_{60}\lambda^2} \sqrt{\frac{12\rho}{Et^2}} = \frac{4.4\pi}{T_{60}\lambda^2} \sqrt{\frac{12Ml^3}{Ebt^3}} \quad (2)$$

Fig. 4 Effect of board thickness on Young's modulus and bending stress of self-adhesive bamboo fiberboard ($\phi=0\%$, $L=10$ mm, $P=20$ MPa).

Fig. 5 Fracture surface images of self-adhesive bamboo fiberboard after bending test ($\phi=0\%$, $L=10$ mm, $P=20$ MPa).

Fig. 6 Effect of hot board thickness on logarithmic decrement and natural frequency of self-adhesive bamboo fiberboard ($\phi=0\%$, $L=10$ mm, $P=20$ MPa).

Here, λ is an eigenvalue, E is a Young's modulus (GPa), I is a geometrical moment of inertia, l is a plate length (m), ρ is a bulk density (kg/m^3), A is a cross sectional area of (m^2), t is a plate thickness (m), b is width (m), T_{60} is a reverberation time (s).

It is found that the difference between the measured value of the natural frequency and the calculated value increases as the plate thickness increases. It is considered that the difference between the measured value and the calculated value occurred because the inside of the bamboo fiber board was not filled with uniform particles but an anisotropic material in which fibrous objects were solidified. Comparing the relationship between Young's modulus and natural frequency in Eq. (1), it can be seen that the natural frequency of this bamboo fiber board is higher than other objects having the same Young's modulus and having Eq. (1). That is, high sound is likely to occur. In addition, at the logarithmic decay rate, since the restraining force between the fibers due to thermal fusion is weak inside the bamboo fiber board, the fibers rub against each other at the time of excitation. It is considered that the internal friction was promoted, and the logarithmic decay rate was influenced by increasing the mass of the molding, that is, increasing the fiber amount.

Fig. 7 Appearance images of self-adhesive bamboo fiberboard by combination ratio of the bamboo powder ($M=7.0$ g, $L=10$ mm, $P=20$ MPa).

Fig. 8 Effect of board thickness on bulk density of self-adhesive bamboo fiberboard ($M=7.0$ g, $L=10$ mm, $P=20$ MPa).

Influence of Combination Ratio of Bamboo Powder

In the previous section, the Young's modulus decreased as the plate thickness increased, and the bending strength also decreased in the region exceeding the plate thickness of 3-mm. This phenomena was considered to be due to suppression of heat conduction to the interior of the bamboo fiber board due to the cavity inside the bamboo fiber board and insufficient thermal fusion of bamboo fibers to each other, so that bamboo powder is mixed with bamboo fiber at the time of hot press forming. We try to fill the cavity between the fibers with bamboo powder to improve the thermal conductivity to the interior of the bamboo fiber board and promote thermal fusion between the bamboo fibers. For the bamboo powder to be mixed, those which were discharged at the time of extracting the bamboo fiber at the machining center were classified with a sieve having an opening of 212- μ m and used. Further, in order to unify with the mass of the whole bamboo fiber board to 7.0-g, the ratio of bamboo powder, which was the compounding ratio, was changed.

Fig. 7 shows the appearance of bamboo powder mixed bamboo fiber board. It can be seen that there is no major difference in the brown area although there is a difference in the portion of the bamboo fiber board. That is, it can be seen that there was no significant change in the thermal conductivity of the bamboo fiber board. Changes in the bulk density of the bamboo fiber board according to the mixing ratio of the bamboo powder are shown in **Fig. 8**. It can be seen that the bulk density slightly increases even if the mixing ratio of bamboo powder changes. From this result, it can be seen that bamboo powder is filled in the cavity between the fibers.

Changes in the Young's modulus and bending strength of the molded body with the mixing ratio of bamboo powder are shown in **Fig. 9**. It is found that the Young's modulus and the bending strength tend to decrease as the mixing ratio of bamboo powder increases within the range where the bamboo fiber board having bamboo fiber. It is thought that the bamboo powder entered between the fibers and weakened the bonds between the fibers as much as possible to reduce the Young's modulus and the bending strength. The SEM images of the fracture surface of the bamboo fiber board is shown in **Fig. 10**. When the mixing ratio becomes high, that is, when the amount of bamboo fiber decreases, the fracture surface tends to be flat, and it is understood that the bonding of the fibers is easy to loosen. Although the molded body strength is lowered by increasing the mixing ratio, the quality of the surface is improved, and the arithmetic average roughness R_a

when the mixing ratio is 100% is about 1- μ m, which is almost the same as the surface roughness of the mold used for fabrication of the bamboo fiber board.

Measurement results of natural frequency and logarithmic decay rate in each bamboo fiber board and the Eq. (1) are shown in Fig. 11. As the mixing ratio of bamboo powder increases, the natural frequency is gentle but decreasing and the log decay rate tends to increase. It is easy to understand that the above tendency will become more pronounced as density increases from Eq. (1). However, using the physical property values obtained from the experimental values, it is understood that when the natural frequency is obtained, the measured value of the natural frequency is larger than the calculated value. The same thing as in the previous article can be mentioned, but since this area contains bamboo powders, since the area of the interface increases, it is thought that the natural frequency also increased with the same plate thickness. It is considered that the logarithmic decay rate was caused by an increase in density.

Fig. 13 Appearance images of bamboo fiber by bamboo fiber length.

Influence of Bamboo Fiber Length

From the previous section, it was found that although bamboo powder is mixed with bamboo fiber, the quality of the molded body improves but the strength decreases. Then, by reducing the fiber length of the bamboo fiber, we will make the fibers dense and study the effect. Fibers having a length of 2.5–15.0 mm were obtained by changing the axial depth of cut during bamboo fiber extraction to 2.5–15.0 mm.

Changes in the appearance of the bamboo fiber board are shown in Fig. 12, and changes in the appearance of the bamboo fiber used are shown in Fig. 13. The plate thickness with the fiber length, and changes in the bulk density before and after the molded body are shown in Figs. 14 and 15, respectively. As the weight of the bamboo fiber boards is the same, the plate thickness increases as the fiber length becomes longer and the bulk density decreases, so in this case as well, it is considered that a cavity is formed inside the bamboo fiber board. It can be considered that the reduction of the brown part area is due to the reduced thermal conductivity of the bamboo fiber board due to the cavity inside bamboo fiber board. It is also found that the bulk density after hot press forming gradually decreases as the fiber length increases. This is due to the bulk density of the fiber before hot press forming, and the bulk density before hot press forming is sharply reduced from the fiber length of 7.5-mm or more. It is thought that the aspect ratio, which is a value of fiber length per fiber diameter, increases as the fiber becomes longer, and the bulk density becomes larger by the frictional force between the fibers. It is considered that the bulk density difference became smaller by being compressed by applying pressure of 20-MPa at the time of hot press forming to this fiber. Although the bulk density decreased despite the application of pressure, this tendency was due to the fact that the bulk density before hot pressing was large and the cavity was formed inside the bamboo fiber board even after pressurization, it was said that it affected the decrease in the bulk density.

Fig. 14 Effect of bamboo fiber length on browning and thickness of self-adhesive bamboo fiberboard ($M=7.0$ g, $\phi=100\%$, $P=20$ MPa).

Fig. 15 Effect of bamboo fiber length on bulk density of self-adhesive bamboo fiberboard ($M=7.0$ g, $\phi=100\%$, $P=20$ MPa).

Fig. 16 Effect of bamboo fiber length on Young's modulus and bending stress of self-adhesive bamboo fiberboard ($M=7.0$ g, $\phi=100\%$, $P=20$ MPa).

Changes in Young's modulus and bending strength of a bamboo fiber board with bamboo fiber length are shown in [Fig. 16](#). SEM images of the fractured surface of the bamboo fiber board is shown in [Fig. 17](#). As the fiber length becomes longer, the Young's modulus and the bending strength of the bamboo fiber board are reduced. In addition, fragments of fibers on the fracture surface cannot be confirmed from the SEM images in case of bamboo fiber board using short fibers such as 2.5 mm in length. It is considered that the fibers were sufficiently bonded by thermal fusion. On the other hand, it can be confirmed that many fibers are pulled out on the fracture surface of the bamboo fiber board using long fibers such as 15-mm in length. Furthermore, many cavities can be confirmed, so that it is understood that the fibers are not adhered sufficiently. Therefore, as shown in the result of [Fig. 16](#), it is considered that the bending strength decreased due to the increase of the fiber length. Similarly, it can be seen from [Fig. 16](#) that the Young's modulus decreases as the fiber length becomes longer.

Measurement results of natural frequency and logarithmic decay rate in each bamboo fiber board and calculated values using Eq. (1) are shown in [Fig. 18](#). It can be seen that as the fiber length becomes longer, the natural frequency of the compact increases

Fig. 17 Fracture surface images of self-adhesive bamboo fiberboard after bending test ($M=7.0$ g, $\phi=100\%$, $P=20$ MPa).

Fig. 18 Effect of bamboo fiber length on logarithmic decrement and natural frequency of self-adhesive bamboo fiberboard ($M=7.0$ g, $\phi=100\%$, $P=20$ MPa).

Fig. 19 Effect of bamboo fiber length on logarithmic decrement and natural frequency of self-adhesive bamboo fiberboard ($M=7.0$ g, $\phi=100\%$, $P=20$ MPa).

moderately and the logarithmic attenuation factor decreases. As the fiber length becomes longer, the number of fibers used in the bamboo fiber board becomes smaller, the abrasion area generated between the fibers decreases and the logarithmic decay rate also decreases.

Influence of Pressure During Hot Press Forming

In the previous section, the strength of the bamboo fiber board was improved by changing the fiber length to increase the bulk density between the fibers. Therefore, if the molding pressure is increased, the adhesion between the fibers is improved and the strength is considered to be high. Here, the effect of molding pressure is investigated.

The appearance images of the bamboo fiber board are shown in Fig. 19. When the hot press forming pressure was low, such as 0, 10 MPa, the brown part was very slight, and almost no thermal fusion of the fibers occurred. Changes in the bulk density of the

Fig. 20 Appearance images of self-adhesive bamboo fiberboard by changing pressure ($M=7.0$ g, $\phi=100\%$, $L=10.0$ mm).

Fig. 21 Effect of hot press forming pressure on bulk density of self-adhesive bamboo fiberboard ($M=7.0$ g, $\phi=100\%$, $L=10.0$ mm).

Fig. 22 Effect of hot press forming pressure on bulk density of self-adhesive bamboo fiberboard ($M=7.0$ g, $\phi=100\%$, $L=10.0$ mm).

compact are shown in Fig. 20. It can be seen that the bulk density decreases with pressure of 20-MPa but decreases with decreasing the pressure. Although a further effect can be expected, the pressure of 40-MPa is the limit in view of the performance of the hot press machine used in this study. Based on the above tendency, the bulk density of the bamboo fiber board with a fiber length of 10-mm in this experimental facility is considered to be the upper limit of 1.3-g/cm³, which seems to be about 2 times the original bamboo material density of 0.7-g/cm³. The fact that the brown part of the bamboo fiber board did not become large was also believed to be because the bulk density decreased at the pressure of 20 MPa or more.

Fig. 21 shows changes in Young's modulus and flexural strength of the bamboo fiber board with hot press forming pressure. It can be seen that the pressure is also similar to the bulk density trend, though the rate of change decreases with pressure of 20-MPa but increases with the pressure. The bending strength and Young's modulus of the bamboo fiber board are considered to be correlated with the density. When the bulk density is low, many cavities are formed, and it is considered that this cavity lowers the thermal conductivity during hot press forming and the strength at which thermal fusion between fibers occurs decreases.

Fig. 23 Effect of hot press forming pressure on logarithmic decrement and natural frequency of self-adhesive bamboo fiberboard ($M=7.0$ g, $\phi=100\%$, $L=10.0$ mm).

The measurement results of the natural frequency and the logarithmic decay rate in each bamboo fiber board and the calculated values using Eq. (1) are shown in Fig. 22. It can be seen that the natural frequency and the logarithmic decay rate decrease as the hot press forming pressure increases. However, the tendency is gentle at the pressure of 20-MPa. This trend is similar to other physical property values, and it can be seen that the situation inside the bamboo fiber board changes at 20-MPa. In low-pressure bamboo fiber board, the distance between the fibers is wide and thermal fusion does not occur, so it can be said that the bonding between the fibers is loose. Therefore, it seems that natural frequency and logarithmic attenuation rate become large. Therefore, it seems that they showed the same tendency as bulk density and Young's modulus (Fig. 23).

Summary

From the above results, it has been reported that the strength of the bamboo fiber board is improved as the strength of the natural fiber-reinforced biodegradable resin-based composite material, which is generally called green composite, increases as the length of the fiber used is longer. Strength prediction by fiber reinforcement theory etc., has been shown (Goda *et al.*, 2004). However, in this study, since a biodegradable resin is not used as a matrix and a heat fusible substance contained in bamboo fiber is used, the closer the distance between fibers is, the more effectively the effect of thermal fusion is exerted. Therefore, it is considered that the strength of the short fiber having a higher bulk density is increased. In the hot press forming pressure as well, the high pressure at which the bulk density is increased likewise resulted in increasing the strength. In addition, as the thickness of the bamboo fiber board became larger, the brown portion decreased, sufficient thermal fusion was not performed, and the strength decreased. Since the strength of the main forming is due to heat, in order to obtain optimum strength, it is necessary to change the amount of heat to be charged according to the volume of the molded body, and the hot press forming time (heating time) not mentioned here is future work to do. We think that it is also necessary to make a formulation for drawing a proper hot press forming condition according to the product shape, size, and number of productions.

On the other hand, it was found that the logarithmic attenuation factor of the bamboo fiber board is largely due to the friction between the fibers. In particular, the change when changing the fiber length was large, it was found that the logarithmic attenuation factor can be changed by changing the fiber length, and it is found that the logarithmic decay rate can be easily manipulated. Even in other natural fiber reinforced composite materials, it can be expected to greatly change the performance and properties of molded bodies by changing the properties of reinforcing fibers. Calculating the natural frequency using the equation to calculate the natural frequency using the bending vibration of the cantilever as a model and the physical property values obtained from the experimental values resulted in irregularities in the measured value and the calculated value. This bamboo fiber board is not filled with uniform particles inside but is an anisotropic material in which fibrous objects are solidified. It was found that the natural frequency of this compact was higher than other objects having the same Young's modulus and satisfying Eq. (1), and it was found that this compact was likely to produce high sound.

Conclusions

In the production of a self-adhesive products using only high-quality bamboo fiber extracted with a machining center, various hot press forming conditions were evaluated on the performance of bamboo fiber board. The conclusions obtained are as follows.

- (1) It was found that the mechanical properties of molded bodies are largely due to the adhesiveness between fibers due to thermal fusibility and are closely related to the distance between the fibers.
- (2) Since the logarithmic attenuation factor is caused by friction occurring between fibers, it is possible to control the logarithmic attenuation factor of the products by controlling the plate thickness. The logarithmic attenuation factor can also be controlled by the fiber length and pressure during hot press forming.

- (3) Within the range of molding conditions in this study, the bulk density is about 1.3-g/cm^3 , which is the limit, which is about 1.9 times the limit of the original bamboo material. From this result, it was found that optimum values exist for the pressure and the fiber length.
- (4) Optimum hot press forming conditions for product when focusing on the static characteristics are to use only fibers having a fiber length of 7.5-mm or less, with a bamboo fiber board having a thickness of 2–3 mm and a molding pressure of 20 MPa or more is there.
- (5) When paying attention to the logarithmic decay rate, it was found that a thin plate with long fibers was suitable as a substitute material for rare wood used for musical instruments.

Introduction

Materials can be classified into several groups depending on their different structure and properties. One of them is the polymers. Polymers have been widely used in various applications including the bulletproof vest, home appliances, compact disk, ropes, toys, and fabrics. In comparison to other types of materials, the polymers have several advantaged characteristics such as low density, good electrical insulator, good resistance to corrosion and some chemicals and economical. However, polymers are known to have low strength as compared to the other materials and not suitable for high temperature applications.

Polymers can be divided into three main categories which are thermoplastics, thermosets, and elastomers. Thermoplastic behaves like plastic, which possesses ductile attribute and can be heated repeatedly, thus can be recycled. Thermoset is more brittle than thermoplastic and cannot be heated repeatedly and decomposes due to crosslinking that occurs with the presence of heat. Thus, thermoset is difficult to recycle.

Meanwhile, elastomer exhibits a unique behavior since it can present as thermoplastics or thermosets, depending on compounding ingredients and processing method. The elastomer can also undergo irreversible crosslinking in polymer chains. As a result, it is found that elastomer is also hard to be recycled. There are several studies that have been done to overcome problems relate to the rubber product waste disposal. For instance, there are several studies discuss about the mixing of recycled elastomers with other materials such as fibre and cement (Thomas *et al.*, 2015; Mazzotta *et al.*, 2017; Medina *et al.*, 2017). In addition, the elastomer also possesses both viscosity and elasticity properties or viscoelasticity and exhibits low Young's modulus value and high elastic deformation that is usually larger than 200% of strain (Askeland *et al.*, 2011). Elastomer is also used interchangeably with the word rubbers.

The natural rubbers are available in two types, which are synthetic and natural. The synthetic rubber is an artificial rubber that is produced through polymerization process of petroleum by-product. The synthetic rubber was invented to reduce the dependencies on the natural rubber during the War World 2. As for today, there are more than 20 types of synthetic rubber that are available for various applications. On the other hand, natural rubber is naturally extracted from the rubber trees through the tapping process. This tapping process is a process of latex secretion by shearing a thin layer of rubber tree's bark by using a special tapping knife. There are more than 2500 known species of plants that can produce latex. In spite of that, only latex produced from *Hevea Brasiliensis* tree is mostly used for rubbery products due to its quality.

Although synthetic rubbers are well known to offer plenty of advantages in terms of mechanical and chemical properties, the natural rubber also possesses advantages over synthetic rubbers. The natural rubber can be considered as green material since it can be continuously supplied by nature as compared to the synthetic rubber, which is derived from the non-renewable sources (Boonkerd, 2017). The price of raw natural rubber is more economical than the synthetic rubber. The price of synthetic rubber is normally fluctuated depending on the current crude oil prices. Other than that, the properties of natural rubber compound can be derived from better formulation and processing. Instead, the natural rubber also allows low heat build-up in dynamic force to make it able to withstand large deformations and grants the natural rubber with the ability to instantly recover when distorted at room temperature (Chandrasekaran, 2010). The application of the natural rubber as main material does not require an extensive maintenance due to its capability of maintaining itself for a long period of time. Additionally, the natural rubber also exhibits inherent damping and spring-like performance in order to reduce the resonant effect. The natural rubber can be bonded with other materials such as metal in order to increase its strength (Lindley *et al.*, 1984).

As one of the largest natural rubber manufactures and exporters, Malaysia has taken an initiative to promote local natural rubber in various fields like construction, automotive and sports. For example, local rubber product is used to produce rubber glove for medical purpose. Malaysian government has established the Malaysian Rubber Board (MRB) and Tun Abdul Razak Research Center (TARRC) to provide the best infrastructure for research and development (R&D) of local NR. The quality and competitiveness of Malaysian natural rubber products, especially in vibration isolation and also for sustainable suspension materials, have been proven to be the best in the world.

One of the example of Malaysian natural rubber application in vibration isolation can be found in the great structure of the Sultan Abdul Halim Muadzam Shah Bridge, Penang. Besides that, most of the Malaysian ports also use the Malaysian-made dock fenders as a bumper to absorb impact from the collision between the boat and the jetty. There are a lot of other examples that prove the natural rubber is an ideal material for the vibration isolation applications in building and also in automotive suspension system (Yu *et al.*, 2001; Kim *et al.*, 2004).

Table 1 Application of the NR due to its properties

<i>Application</i>	<i>Properties</i>
Surgical gloves	Tear resistance, strain induce crystallization
Blow-out preventers, hoses, connectors, inner tubes, and bladders.	Oil-resistance, gas impermeability
Tires	Tear strength, wet-grip, rolling resistance/abrasion
Bearings	Elasticity, low dissipation factor, wear resistance
Shoes	Damping
Suspension system	Damping, stiffness

Soft steel	9.18
Rolled aluminum	22.6
Hardened steel	284
Vulcanized rubber	44,800

Natural Rubber as the Sustainable Green Materials for Suspension Materials

The natural rubber has been extensively used in various applications due to its distinctiveness over other materials like excellent physical properties, renewable sources origins, and economical. The elasticity and flexibility of the natural rubber are the main reasons for this material to be applied in various fields especially in the engineering area. In addition, the ability of the natural rubber to withstand exceptional large stress without permanent deformation or fracture has ensured the survival of the materials itself and makes it suitable to be used in various environments, except for the environment that exposed to the ozone and chemicals. Some application of the natural rubber according to its typical properties has been listed in [Table 1](#).

The basic strength of the natural rubber is actually depending on its basic chemical structure. Like any other natural products such as cellulose and silk, the natural rubber can be categorized as high polymer material. The natural rubber is classified in the hydrocarbon group with 99% of its builds up is from poly-isoprene arranged of high cis-1,4 configuration. The presence of such chemical configuration gives the natural rubber a glass transition temperature of approximately -75°C , which makes the natural rubber to become extremely elastic and works very well at room temperature ([Chandrasekaran, 2010](#)). It also manifests the natural rubber ability to undergo strain-induced crystallization that leads to excellent tensile strength and great resistance towards tearing and abrasion. In addition, the natural rubber also has high bulk modulus due to relatively strong intermolecular forces in the compound with the value around 10,000 MPa and Poisson's ratio value of 0.499 ([Tabor, 1994](#)). Due to the high bulk modulus value, the natural rubber can be assumed to be nearly incompressible when compressed in the solid state.

Carter and Paul in 1991 described the mechanical properties of the natural rubber in terms of stress and strain curve. Based on the open literature, the curve exhibits two different phases; the large elongation at low-stress phase and the small elongation at large phase. During the first phase, low stress is needed to stretch the coiled polymer network and causes the curve to exhibit small Young's Modulus reading. Besides that, in this state, the natural rubber is able to return to its original shape or length. Meanwhile in the second phase, as the strain is continuously applied, the natural rubber networks start to uncoil and stretch to its maximum. Thus, higher stress is needed to stretch the natural rubber, which resulting in higher Young's Modulus reading. In response to the applied stress, some of the natural rubber networks have become fully extended and unable to withstand the applied stress.

Then, the natural rubber is also known for its superior ability to store energy as compared to other materials as shown in [Table 2](#). A curve of complete load-unload cycle for rubber compound. The retraction curve is produced under the extension curve, which indicates the rubbers behavior during the unloading process. The differences between the extension and the retraction stress values under similar strain value represent the hysteresis in rubber. This hysteresis behavior is occurred due to internal friction between the rubber particles, which reacts towards extension and retraction. During the extension of rubber, work increases as the area under the curve increases and high energy is required to perform work. Meanwhile, during the retraction, less energy is needed to perform work. Thus, the excessive energy that equivalent to the area in the curve loop is converted into heat. The larger loop indicates that higher energy is released. Thus, it indicates low elasticity of the natural rubber. The hysteresis can be observed in both natural and synthetic rubbers. In the case of the natural rubber, hysteresis is highly affected by the types of reinforcing filler, fillers amount and the test strain rate. The genuine natural rubber exhibits less hysteresis than the filled the natural rubber since it is more elastic.

Other than that, the natural rubber is also known to exhibit stress softening behavior under repeated loadings. The softening in rubbers, also named as Mullins effect, was extensively investigated by Mullins and his colleagues. Mullins in 1948 reported that the

softening effect was only found in filled rubber and directly proportional to the stiffening ability of the NR. However, an extended study by Harwood *et al.* (1965) reported the occurrence of softening in the filled the natural rubber as well as in unfilled natural rubber compounds. The softening in rubber, which is often observed after the first cycle, has shown the reduction of stress at the continuous repeated loading with similar maximum strain as showed in a study conducted by Diani *et al.* (2009). The researchers also found that the softening effect increased with the increasing strain in the carbon filled the natural rubber compound. The researcher also observed that Mullins softening was highly depended on the filler loading. The natural rubber compound with higher filler loading experienced the softening effect at lower strain as compared to the compound with less filler content.

In contrast to the softening effect caused by stress-induced, the crystallization happens with the application of strain at room temperature by changing the amorphous state into semi-crystalline state. The ability of the natural rubber to crystallize is often related to its high regularity of chemical structure. In order to crystalize, the natural rubber chains stretch up to align towards the direction of applied strain and causing the entropy to decrease. The crystallite regions in the natural rubber act as self-reinforcement. It is similar as nanoscopic fillers or crosslinks that help to improve the mechanical properties of the natural rubber, such as the ultimate strength and tear resistance (Spratte *et al.*, 2017). Besides that, the formation of the crystallization is also found in both filled and unfilled vulcanized natural rubber (Mullins and Tobin, 1957; Trabelsi *et al.*, 2003).

There are several factors that influence the strain-induced crystallization in the natural rubber: crosslink density, temperature, strain rate, fatigue, crack tip and the addition of fillers. A research conducted by Rault *et al.* (2006) proved that the fillers, especially the carbon black could act as the strain amplifier as proposed by Mullins and Tobin (1965). Spratte *et al.* (2017) studied the influence of strain-induced crystallization in the natural rubber composites reinforced with carbon black and silica to the mechanical and temperature measurements. The researchers verified that the natural rubber with carbon black compound exhibited the highest degree of crystallization, followed by the natural rubber with silica/silane system compound and the natural rubber reinforced with silica without silane system compound. In addition, Poompradub *et al.* (2005) as cited in Huneau (2011) has investigated the stress-strain behavior and the strain-induced crystallization of the natural rubber at different carbon loadings (0, 20, and 40 phr). Throughout the studies, the researchers found that SIC appeared at lower strain in the natural rubber with carbon black and the crystallites size was slightly difference in the natural rubber with different carbon black loadings. In addition, the researcher also agreed about the existence of higher disorientation in carbon black filled N natural rubber compound rather than the unfilled natural rubber compound. Huneau (2011) concluded that the addition of carbon black reduced the global stretch ratio to the crystallization onset in the stretched natural rubber compound.

Modified Natural Rubber

The natural rubber alone is inconvenient for the customer's usage, especially in its raw state. In fact, the natural rubber is well known to have low resistance towards weather instead of having poor wet grip properties, which are essential in vehicles tires application and high solvent solubility (Gelling, 1991; Wan *et al.*, 2010). Thus, modification of rubber compound is the best solution for researchers to enhance the natural rubber properties depending on its application, which can be conducted by altering the compound either physically or chemically. The physical modification can be divided into three methods; by removing protein contents in the natural rubber through deproteinization, adding processing aid or blowing agents in the natural rubber compound (Merabet *et al.*, 2012), turning the natural rubber into a thermoplastic elastomer by adding up the polypropylene, and mixing the vulcanized and non-vulcanized rubbers as a compound. Meanwhile, the chemical modification is done by rearranging the molecular chain of the natural rubber in various ways such as depolymerizing and adding a new functional group into NR molecular chain. The epoxidized natural rubber (ENR) and constant viscosity rubber (SMR CV) are the examples of chemical modified the natural rubber that have been extensively used in rubber industries. Since this study focusing on ENR and SMR CV rubbers, only these types of the natural rubber will be explained later.

Epoxidized Natural Rubber

The epoxidation method has become a major option as it exhibits a simple reaction procedure and effective compounding cost. The epoxidation process involves the addition of oxygen atom into a proportion of carbon-carbon double bonds through the addition or substitution reaction to produce the epoxide ring. This process becomes more effective when it is conducted at the latex stage by using several chemicals such as performic acid, hydrogen peroxide and formic acid. Performic acid is a soluble liquid with strong oxidizing properties. The natural rubber can be epoxidized up to 75 mol% under a controlled condition to produce the natural rubber compound with superior properties such as better resistance towards the hydrocarbon oil and high mechanical properties. However, the epoxidation of the natural rubber up to 100 mol% produces hard thermoplastic materials (Baker *et al.*, 1970).

The advantages of ENR over other modified the natural rubbers are the outstanding damping properties, high resistance to hydrocarbon oils, good strength properties, high wet grip and lower air permeability. For these reasons, ENR has been used in various applications such as automotive tire tread, adhesive, bladders, vibration mount, and shoe soles. Besides that, epoxidation process supplies ENR with high glass transition temperature and high polarity. High polarity in ENR makes it suitable to be used with vulcanized the natural rubber of different polarities and bonded with metals (Baker *et al.*, 1970). Currently, only two types of ENR are commercially used, which are ENR 25 and ENR 50. In Malaysia, ENR is commercialized by Malaysian Rubber Board (MRB) under the name of Ekoprena 25 and Ekoprena 50.

Table 3 Grades chart for ENR 25

Parameter	ENR 25	ENR 50
Epoxidation level, %	25 ± 2	50 ± 2
Ash (max wt%)	0.50	0.50
Density (Mg/m ³)	0.97	1.02
Solubility parameter (Jm ⁻³) ^{0.5}	17.4	18.2
Lovibond color	4.5	3.5
Mooney viscosity ML(1' + 4'') 100°C	70–100	70–100

Table 4 Physical properties of ENR 25 and ENR 50 at 60 phr of carbon loading

Property	ENR 25	ENR 50
Tensile strength (MPa)	22.4	21.0
Elongation at break (%)	497	465
Rebound resilience, at 23°C (%)	39.7	25.9
Compression set (72 h, RT) (%)	16.5	20.5
Tear strength (N/mm)	94.0	57.0

Table 3 presents the grades chart of ENR 25 and ENR 50 according to their parameters. The difference between ENR 25 and ENR 50 is the epoxidation level: 25 mol% epoxide and 50 mol% epoxide. The low epoxidation level causes ENR 25 to have low glass transition temperature at $-45 \pm 2^\circ\text{C}$ as compared to ENR 50 at $-20 \pm 2^\circ\text{C}$. Higher epoxidation level causes the glass transition temperature and damping to increase, thus reducing the resilience of the rubber compound (Pire *et al.*, 2010). It is very suitable using for sustainable suspension systems.

In a comparison study of vulcanized ENR filled with 60 phr of carbon black, and (Wan *et al.*, 2010) found that the ENR 25 exhibited better tear strength and good resilience at room temperature as compared to ENR 50. Besides that, it was also found that the tensile strength of ENR 25 was slightly higher than ENR 50. Davies *et al.* (1983) also found that the degree of SIC also reduced when the level of epoxidation was more than 50%. The physical properties of ENR 25 and ENR 50 are summarized and presented in **Table 4**.

Standard Malaysian Rubber Constant Viscosity

Variety grades of coagulated the natural rubber compound are available and all of them have been technically specified according to the American Society for Testing Materials (ASTM). All coagulated compounds are measured based on their physical properties such as the dirt content and the method of production. However, the detailed description of the natural rubber can also be obtained through the respective rubber producing countries. As in Malaysia, the basic grades of coagulated natural rubber compound are promoted as Standard Malaysian Rubber (SMR). The SMR 5, SMR 10, SMR 20, SMR GP and SMR L are the examples of the natural rubber compounds under the SMR scheme. In order to obtain the consistence viscosity of the natural rubber latex, a specialized grade with a constant viscosity (SMR CV) is introduced. The constant viscosity properties are also available for the SMR grade and the products are labelled as SMR 10CV and SMR 20CV.

The SMR CV grade contains about 0.15% of hydroxylamine hydrochloride or hydroxylamine neutral sulphate. The main purpose of the chemicals addition is to maintain the viscosity of the raw rubber liquids in order to prevent hardening during storage period. Rubber hardening occurs due to the reaction of particle crosslinking process with the low humidity of storage surrounding. SMR CV-50 and SMR CV-60 are the examples of SMR CV grade that are commercially available. The only difference between both types of constant viscosity the natural rubber is their Mooney viscosity values, which are 50 and 60 Mooney unit. The technical specifications of SMR CV-60 are tabulated in **Table 5**.

The SMR CV is more expensive as compared to other grades of the natural rubber. However, the usage of SMR CV helps to reduce the energy consumption during processing. The constant viscosity properties enhance the processing step of dry the natural rubber by allowing direct mixing without premastication step. Thus, it reduces the required mixing energy as well as the production cost (Lindsay, 2012). Other than that, the texture of SMR CV rubbers is softer than any other technically specified rubber and makes it easier for other ingredients to disperse uniformly during the mixing process. Thus, it reduces scraps and the compound probability to be rejected. SMR CV rubbers also exhibit good green strength and better resistance to chipping and chunking, which are important for tires application (Rodgers, 2015).

Rejab *et al.* (2013) studied the effects of increasing carbon filler percentages (0%, 20%, and 45%) in four types of rubbers, which were the SMR CV-60, ekoprena, pureprena, and synthetic rubber. The authors observed that all rubbers with the highest

Table 5 Grades chart for SMR CV-60 according to Tenaga Gemas Sdn Bhd (2017)

Parameter	SMR CV60
Dirt (max wt%)	0.02
Ash (max wt%)	0.50
Nitrogen (max wt%)	0.55
Volatile matter (max wt%)	0.50
Wallace rapid plasticity (P_n) (min)	N/A
Plastic retention index (PRI) (min)	60
Lovibond color	N/A
Mooney viscosity ML(1' + 4") 100°C	60(±5)

Table 6 Tensile properties of the SMR CV-60 and ENR 50 at various blending ratios

Property	Blend ratio, MPa (SMR CV-60 to ENR 50)				
	0/100	25/75	50/50	75/25	100/0
Tensile strength (MPa)	10.70	9.50	12.50	14.00	13.20
Elongation at break (%)	700	700	700	700	700
Tensile modulus at 300% of elongation (MPa)	1.65	1.60	1.60	1.70	2.60

percentage of carbon yielded the best results for tensile, compression, hardness and static stiffness. Meanwhile, in another study conducted by Sasitaran *et al.* (2016) on the preparation and characterization of cross-linked SMR CV-60 and ENR 50 blend, the authors found the change in the properties of cross-linked pure and blends rubber. A tensile test was conducted on the blend of SMR CV-60 and ENR 50 with the blending ratios of 0%/100%, 25%/75%, 50%/50%, 75%/25% and 100%/0%. The authors found that the cross-linked rubber presented better tensile properties as compared to the non-cross-linked rubber in terms of tensile modulus at 300% elongation, tensile strength, and elongation at break. It occurs due to the formation of three-dimensional network that limits the molecular chain movement and resulting to stiffer and stronger rubber chains. The tensile properties of the rubber blend are presented in Table 6.

Compounding and Processing Pure and Modified Natural Rubber for Sustainable Suspension Materials

The natural rubber is known to be weak in its raw state and can only be improved through compounding. Compounding can be defined as a process of adding other ingredients into raw elastomers and may include several compounding processes. Instead of enhancing the properties of the natural rubber compound, the added ingredients also affect the processing behavior such as the number of mixing cycle, mixing time and rate of extrusion. These processes highly influence the properties of the rubber compound in terms of its static and dynamic properties. For example, Payne (1965) found that the increased in mixing time reduced the dynamic modulus and viscosity as well as the phase angle value at a moderate amplitude of oscillation for vulcanized rubber reinforced with the carbon black. This finding proved that the dynamic properties of vulcanized rubber could be affected by the mixing time and it was associated with the dispersion of the carbon black in the compound. Thus, this sub-article will elaborate more on the compounding ingredients and their effects on the NR and also the processes to produce the rubbers compound (Salim *et al.*, 2016).

Compounding Ingredients

The rubber compound is a combination of rubber with different ingredients at specific composition and manufacturing process. The main purpose of rubber compounding is to enhance the properties of the raw rubber to match with customer's requirement and application. Usually, the compounding formulation is designed to meet the physical and chemical requirements of the product. As a reference in material selection of rubber compound, the compounding ingredients can be divided into five categories as follow: elastomer types, vulcanizing system, anti-degradant system, reinforcing system, and special materials. Each of the ingredients plays an important role in changing the properties of the rubber compound. The "phr" or "pphr" unit stands for unit per hundreds of rubber and it is used as the measurement unit in a rubber formulation.

Elastomer exists in two types: natural or synthetic rubber. Each of the elastomer possesses specific characteristic and requires different parameters of compounding process such as the vulcanizing mixing period. NR offers a wide range of grades, which can be divided into three basic types: technically specified rubber, visually inspected rubber, and specialty rubber. Besides that, the

natural rubber is also available in various forms such as sheets, block rubbers, and preserved latex concentrations. The selection of elastomer type and form is made depending on the rubber product application and processing method as well as suitability with the required environmental service.

Vulcanization is a process of improving the properties of rubber compounds by creating a new polymer network through crosslinking between the polymer chains (Coran, 2013). The main function of the vulcanization system is to convert the physical properties of raw rubber from tacky into non-tacky and elastic rubber. The vulcanizing system needs three important ingredients for the system to function efficiently, which are the vulcanizing agents, accelerator, and activator.

Vulcanizing agent is the most important ingredient in this system as it is used to strengthen the rubber compound properties through the vulcanization process. Normally, this process is conducted by heating the mixture of raw rubber with vulcanizing agents at specific vulcanization time in a pressurized mold. Three types of the vulcanizing agent are extensively used; the sulphur, insoluble sulphur, and peroxides. After all, sulphur is the most generic vulcanization agent as it is easily available, inexpensive and effectively enhanced the rubber compound (Chandrasekaran, 2007). It helps to increase the crosslink density of rubber compound, which resulting in the increase of rubber properties such as tensile strength, tear strength, static and dynamic modulus, hardness, and fatigue life.

The accelerator is added into the rubber compound to boost up the efficiency of sulphur in the vulcanization process. The main purpose of accelerator addition in the rubber compound is to increase the rate of crosslinking between the sulphur molecules and the rubber chains. The accelerators are classified into two, which are organic and inorganic. The examples of accelerators are n-cyclohexylbenzothiazole-2-sulphenamide (CBS), t-butyl benzothiazolyl sulphenamide (TBBS), morpholino thio benzothiazole (NOBS), n-oxydiethylenbenzothiazole-2-sulphenamide (MBS), tetrabutylthiuram disulphide (TBTB), tetramethylthiuram disulphide (TMTD), sodium diethyl dithiocarbamate (DETC), hexamine, and many more (Chandrasekaran, 2007; Kothandaraman, 2009). The organic accelerators are often consumed in the rubber industry since they can reduce the amount of sulphur and less curing time. Some of the accelerators especially the sulphonamides classes (CBS, TBBS, and NOBS), help to speed up the curing time without reducing the scorch safety, even at the higher parts per hundreds rubber (Salim *et al.*, 2014).

The activator, such as zinc oxide and stearic acid, acts as a catalyst to boost up the sulphur and accelerator performance during the crosslinking process. Besides that, the activator also helps in dispersing the sulphur evenly in order to prevent the agglutination and the blooming phenomena, which can occur due to excessive sulphur content in the natural rubber compound. Occasionally, the selection of vulcanizing systems such as the accelerator and activator composition and the rate of the vulcanization are likely depended on the types of elastomer used: where it was known that the natural rubber could be vulcanized faster than some other elastomers such as SBR (Rodgers and Waddell, 2013).

Some of the rubber products are used in the applications that expose to elevated temperatures, hazardous gases, and weather changes. The exposure to this kind of conditions for several periods can affect the mechanical properties of the rubbers and resulting to the fatal failure when repeated load is applied. Besides that, in thermosetting elastomer especially for the natural rubber, the formation of carbon-carbon double bond increases the probability of the natural rubber to be subjected to oxygen and ozone attack. Prior to that condition, the anti-degrading system is included in the rubber compounding formulation as a protection against the degradation causes by those conditions and it is followed the regulation of the suspension system, basically.

The anti-degrading can be divided into two; the anti-oxidant and the antiozonant. The effective amount of anti-oxidant in rubber compound is around 1–2 phr (Institute, 2000). The anti-oxidant is available in two types, which are the non-staining antioxidant and staining anti-oxidant. The staining anti-oxidant is extensively used as general anti-oxidant due to its efficiency to evade the oxidation against heavy metals such as nickel and copper ions. The low volatility of staining anti-oxidant enhances the durability and the temperature stability in the rubber compound. Besides that, it also improves fatigue resistance properties and gradually reduces the color of the compound. The non-staining antioxidant is used to solve the discolouring problem but eventually, provides less effective anti-aging action.

On the other hand, rubber compound requires 0.5–5 phr of antiozonant ingredients to work effectively against the reaction with the ozone. There are various types of antiozonant; however, the wax type is known to be the most efficient. In a static state, the wax usually blooms into the rubber product surface, to form a protective layer to prevent the rubber from reacting with ozone. The ozone outbreak usually happens in the strained state, where the protective layer breaks due to applied force. However, for saturated rubber such as EPDM, SBR, and NR, it contains polymeric antiozonant, which makes it prone to ozone.

The addition of vulcanizing agent and anti-degrading alone are not sufficient to acquire the desired properties in producing viable rubbery products. Thus, the reinforcement of fillers becomes the solution. Reinforcing can be defined as the influence of fillers on the physical properties of the natural rubber. The fillers, which are cheaper than the main materials, are added to reduce the manufacturing cost, improving the processing step, and enhancing the mechanical and thermal properties of materials.

The fillers can be divided into three classes: reinforcing, semi-reinforcing, and non-reinforcing. The reinforcing filler is able to improve the mechanical properties of rubber compound such as tensile, tear, and abrasion. The semi-reinforcing fillers also work well as the other reinforcing fillers except for abrasion resistance properties. Meanwhile, the non-reinforcing fillers only function as a diluent as they do not affect the properties of the natural rubber compound. The reinforcing filler is also available in two types, which are the black and non-black filler. The carbon black is the example of black fillers, while zinc oxide, magnesium carbonate, silica, and clays are the example of non-black fillers. Since carbon black is extensively used as filler for the sustainable suspension systems, its influences in the natural rubber compound will be explained further in the other subsection.

Fig. 1 Flow of rubber compounding process.

Table 7 General properties of rubber mixers according to ASTM 3182

Parameter	Types of mills		
	Standard mills	Standard internal mixer	Standard miniature internal mixture
Roller diameter, mm	150–155	N/A	N/A
Chamber volume, cm ³	N/A ^a	1575 ± 50	N/A
Mixer head volume, cm ³	N/A	N/A	120
Loading capacity, cm ³	N/A	1170 ± 40	64
Rotor speed, rpm	24 ± 0.50	77	60 + 3,–0

^aN/A = Not available.

Specials materials can be defined as inclusion of other special purpose materials such as the processing aid, softeners, and plasticizers, fire retardants, blowing agents, resins, pigments, and dyes. Those special materials are used to improve the efficiency of rubber compound processing. Besides that, it also helps to reduce the viscosity of rubber compound, which is important to provide better extrusion characteristic during processing.

Normally, those materials are added in small parts per hundred grams of rubber to avoid any effect neither in physical or chemical properties of the rubber compounds. It also helps to disperse filler evenly in order to maintain the physical strength of the compound. Examples of processing aid that have been used extensively in rubber compounding industry are paraffin, fatty acid, low viscosity naphthenic oil, factice and homogenized resins.

Instead of the compounding ingredients, it is found that the compounding process also affects the properties of the rubber compound. Mostly, the compounding process is conducted following the guidelines describe in ASTM 3182. The standard provides a complete reference of preparing a rubber compound including the procedures, precautions, and general equipment features for the involved process. **Fig. 1** shows the flow of the compounding process for rubber compound, which starts by weighing the ingredients to the correct amount according to the specified recipe for rubber.

The next process includes the mixing of all ingredients at a specific period. There are three types of general mixing equipment, which are the standard mill, the standard internal mill, and the standard miniature internal mixer. All these mixers have different properties in terms of their roller diameter, speed, and mill rolls temperature and mixing procedure as shown in **Table 7**. In the standard mill, all compounds and rubber are mixed on the slow roll at a constant temperature. Meanwhile, for the internal mill, the compound is prepared in two stages; firstly, in the internal mixer and secondly in the standard mill. Rubber is cut into smaller pieces to allow fast feeding at required discharged temperature. Then, the compound is sat on the flat metal surface to cool down before proceeding to the second stage by using the standard mill. As for the miniature internal mill, the mixer head is preheated 5 min before compounding process starts. The ingredient is mixed together at three different roll separations 0.5 mm, 3 mm, and 0.8 mm. All batch of rubber compound needs to be tested on viscosity and process ability by referring to ASTM D1646 and D6204. Then, the test sample is taken from the master batch to determine the vulcanization characteristic based on ASTM D2084 and D5289.

The next process is the forming process, where the rubber compound is shaped in the form of sheets or pallets, depending on the application or the test that will be conducted. The general relative humidity for sheeted rubber compound must not more than 55% from 1 to 24 h at 23 ± 3°C during the process, unless it is set to a certain value. After that, the process is proceeded with the curing process at the specific temperature and period. The sheeted compound is cut a bit smaller than the size of the mold cavity and placed on the flat, clean and dry metal surface with the mark of milling direction. The mold is preheated in the closed press for 20 min to the curing temperature before inserting the rubber pieces. After the mold achieves the required curing temperature, the rubber pieces are quickly inserted to avoid heat loss. The mold is placed in the closed press with a minimum pressure of 3.5 MPa at the specified curing time. The curing time is calculated from the moment the pressure is completely applied until the moment of the pressure is completely released.

Conclusion

This article has discussed in details of the effects of compounding ingredients toward properties and the process ability of sustainable suspension materials. The compounding ingredients can be categorized into five: elastomer types, vulcanizing system, anti-degradant system, reinforcing system, and special materials. All these ingredients gave specific effects on the compound. In addition, this sub-article also explains all the related processes in rubber compounding.

Introduction

Friction stir welding (FSW) is one of the advancements in the solid-state welding techniques, which offers the joining of similar as well dissimilar metals, alloys, and thermoplastics. FSW has attracted the attention of today's researcher/scientists due to its lower thermal degradation on the joint. The rotating pin in the rotor generates heat due to friction between rubbing surfaces and mechanical mixing also ensures good bonding at the joint (Vijendra and Sharma, 2015). The input process variables of FSW such as rotational speed, indentation depth, longitudinal speed or feed, axial load, and tilt angle affect the mechanical, thermal, and morphological properties. It has been observed that porous/blow holes are generated at low rotational speed due to improper bonding at the interface of the joints (Jaiganesh *et al.*, 2014). The mechanical properties of the friction welded parts are largely influenced by the rotational as well as longitudinal speed. From visual inspection it has been studied that more defects take place at the retarding side of the sample joint than the advancing side (Eslami *et al.*, 2015). Some studies have reported that the vertical coordination of glass fiber in the nylon66 parts does not affect the mechanical properties of the FSW joint with the vibrating tool. The properties of the joined matrix define the properties of the joint (Węglowska and Pietras, 2012). Some researchers have reported investigations of mechanical, thermal, and metallurgical properties for frictionally welded joints (Taylor *et al.*, 1989; Yilbas *et al.*, 1995; Kostka *et al.*, 2009). The deformation and microstructure at the welded joints were investigated using scanning electron microscope and optical microscope to check influences of input process parameters (Gao *et al.*, 2015; Sluzalec, 1990). Welding of acrylonitrile butadiene styrene (ABS) or Nylon 6 to itself or welding of ABS to high density polyethylene has been reported as a success. The influences of using a threaded pin for FSW of nylon 6 sheets have enhanced mechanical mixing at the joint interface (Stokes and Hobbs, 1993). Friction inertia welding is widely accepted in aerospace applications (Stokes, 1993; Yilmaz *et al.*, 2002). The reinforcement of nanocomposite (carbon nanotube, graphene, and nanosized metal powder) with polymers is responsible for the improved mechanical and metallurgical properties (Rotundo *et al.*, 2010; Panneerselvam and Lenin, 2014; Attallah, 2012; Raab *et al.*, 2015; D'Alvise *et al.*, 2002). For transferring such development technologies from lab scale to production house, it is mandatory to justify the controlled physical characteristics of the obtained part each time. For such justifications, process capability indices can be of immense help in prevention of the manufacturing of defective items and can also be used for the improvement of the process (Healy *et al.*, 1976). Further, statistical quality control and the capability methods are effective for identifying quality problems and thereby eliminating them from the process (Hoseinlaghab *et al.*, 2015).

The reported literature reveals that welding of similar and dissimilar metals, alloys, and thermoplastics is possible by varying process parameters or reinforcement. Some of the studies have reported process capability analysis of different manufacturing processes. However very little has been reported on use of statistical quality control for FSW of dissimilar thermoplastic materials. In this study the FSW process was controlled by varying the rotational speed (rpm), transverse speed (mm/min), and plunge depth (mm) for melt flow compatible dissimilar thermoplastic composites. Further, the welded joints were subjected to tensile, flexural, and hardness tests. Based upon the optimized input setting, repetitive experiments were performed and tensile, flexural, and hardness testing was carried out. The results are plotted as X-chart, process capability histogram, and normal probability curves for investigating the process capability.

Experimentation

The approach of FSW by using consumable pin is shown in Fig. 1. ABS and polyamide (PA)6 in granular form (size: 1–1.5 mm) have been selected and blended with Al metal powder (size: 50 μ m). The blends of Al metal powder and thermoplastic were poured into a melt flow indexer for investigating the variations of Al content on the melt flow index (MFI). The results of MFI suggested that ABS with 15% Al content and PA6 with 50% Al content were observed 11.57 g/10 min and 11.97 g/10 min, respectively. So, upon similarity in MFI, ABS-15%Al and PA6-50%Al have been considered as the final composition for further experimentation. The feedstock filaments of ABS-15%Al were extruded by twin screw extruder setup under 220°C barrel temperature, 30 rpm screw speed with 20 kg load and PA6-50 Al under 245°C barrel temperature, 20 rpm screw speed with 15 kg load. Further 3D printing (cylindrical surface: 50-mm diameter and 50-mm length) by using fused deposition modeling has been performed for both thermoplastic composites under 30 mm/s printing speed, covering by 6 perimeters at 250°C temperature.

The pilot experimentation involves examining weldability of Al reinforced substrate using melt flow compatible consumable tool under rotational speed range of 1000–1500 rpm, traverse speed of 30–50 mm/min, and consumable pin depth up to 4 mm.

Fig. 1 Methodology for friction stir welding by using consumable pin.

Table 1 Tensile, flexural, and shore D hardness of joints

<i>Trial</i>	<i>Peak tensile strength (MPa)</i>	<i>Peak flexural strength (MPa)</i>	<i>Shore D hardness</i>
1	100.1	225.5	83.0
2	100.6	224.1	82.5
3	101.1	225.4	82.5
4	100.4	225.8	83.0
5	100.5	224.9	83.5
6	100.7	225.6	83.0
7	100.6	224.9	82.5
8	100.7	225.1	83.0

Fig. 2 X-chart for peak tensile strength.

Further three levels of rotational speed (1000, 1200, and 1400 rpm), traverse speed (30, 40, and 50 mm/min) and consumable pin depth (2, 3, and 4 mm) have been selected for deciding the optimum set of input process parameters. It has been observed that maximum value of tensile strength, flexural strength, and shore D hardness were obtained at 1400 rpm, 50 mm/min feed rate, and 3 mm consumable pin depth. Under the suggested input process parameter setting, 8 repetitions of FSW have been performed for investigations of process capability analysis (see [Table 1](#)).

Fig. 3 X-chart for peak flexural strength.

Fig. 4 X-chart for shore D hardness.

Fig. 5 Process capability histogram for peak tensile strength.

Results and Discussion

Based upon observations in Table 1, Figs. 2–4 respectively show the X-chart for peak tensile strength, peak flexural strength, and shore D hardness. As observed from Figs. 2–4 for peak tensile, peak flexural, and shore D hardness as output the plotted data lies well within the upper control limit and lower control limit, which have been judiciously selected based upon industrial applications.

Further for process capability analysis the peak tensile strength data (Table 1) has been used to plot process capability histogram for eight repeated set of observations (see Fig. 5) and process capability indices Cp and Cpk were calculated.

As observed from Fig. 5 for peak tensile strength data Cp and Cpk values near to 1 ascertain that the process is under statistical control. Similar observations were made for peak flexural and shore D hardness.

Summary

In the present study statistical analysis on a novel route for joining the dissimilar thermoplastic based composite materials by FSW with consumable tool for batch production has been reported. The X-chart, Cp and Cpk values near to 1 ascertain that the proposed settings for this novel route are under statistical control and may be fixed as industrial standard for future reference.

Introduction

Geospatial technology is an advanced technology that provides geographical mapping and analysis about the earth and human societies. This technology has been widely used in daily life and it is evolving over time. It has been applied in a variety of uses for the purpose of facilitating human activities. The daily application of geospatial technology such as the Global Positioning System (GPS), Geographic Information System (GIS), and remote sensing have been significantly increasing especially in the field of monitoring systems (Albert, 2012).

Geospatial technology consists of two important components, which are computer hardware and software. These two components are used to collect, manipulate, store, analyze, and display geospatial data that has been gathered. This technology is evolving and being adapted with other technologies for the usage of the human particularly in visual positioning such as GPS, GIS, remote sensing, and other visualization systems. They have become available to nearly everyone through a variety of devices. Consumer demand has been increasing for these devices as a way to manipulate and display geospatial information, which can be seen over the past decade. For example, the implementation of GPS data with digital maps has been used in vehicle navigation devices and is used every day for navigation and directional purposes by many people worldwide. The application of Google Earth launched in 2005 has enabled everyone to manipulate digital maps and geospatial data (Folger, 2010).

GIS can be described as a computerized information storage, processing, and retrieval system that is equipped with hardware and software. It is specially designed to cooperate with geographical referenced data and corresponding attribute information. It is also an organized collection of computer hardware, software, and geographical data, which is designed to efficiently capture, store, update, manipulate, analyze, and display all forms of geographical referenced information. There are three steps in GIS spatial analysis, which are preparation of an appropriate model, proper visualization, and analysis of data from a simple map to statistical models. The modern GIS uses detailed digital maps, satellite images, and computer models as its data sources in locating the position that is necessary to provide appropriate reaction, so that all the data that have been collected can be interpreted in a simple way.

According to DeMers (2008), there are two basic concepts of GIS. The first one is that the features have attributes associated with them. A GIS tells us “where” and “what” it is. Geographical location replies to “where” something is and “what” it is. Thus, GIS can clearly distinguish itself from nongeographical spatial data management system like Computer Assisted Cartography (CAC) or Computer Aided Design (CAD), which do not use georeferenced data. CAC is excellent for visualization and can be used specifically for mapping purposes while CAD is excellent for producing architectural drawings and simplifying editing process. It can also perform map analysis.

The second basic concept of GIS is that the collected information must be separated into layers. GIS features like rivers, roads, or forests are usually stored in different layers so that they can be added or taken off during GIS projects as needed. Layers are usually called coverage or databases and in most cases they consist of several computer files that have the same name but with different extensions. Layers represent the information of particular classes and can be combined to create new layers, which contain specific selected information to a particular query on the GIS. Basically, there are three fundamental features by which any layer can be presented.

Nowadays, GIS has been widely used in various applications and fields such as scientific investigations, resource management, asset management, environmental impact assessment, urban planning, cartography, criminology, history, sales, marketing, and logistics. Topographic and mapping (cartography) visualization is one of the components that can be accessed using GIS. GIS can display the Earth in realistic, three-dimensional perspective views and animations that convey information more effectively to the audiences as compared with conventional two-dimensional of static maps.

The application of GIS mapping in mine suspected areas can provide effective management of suspected mines. It can also enhance mine security, offer interactive access, and manage the database. In addition, it also enables the management to have statistical information analysis and visualization of digital maps by multimedia data. The implementation of GIS mapping resulting two-thirds of 1230 km² of area have been identified covered by flood from 26,960 km² of contaminated mine areas. The implementation of GIS also manages to determine active landslides that occurs, which nearly above 2000 locations or points. The Mine Action Center (BiH) has stated that there are more than 100,000 mines. In this situation, dangerous areas can be labeled as floods triggered mine. In some recorded cases, the explosion of mines that are shifted by floods have occurred in the area of Brcko District in the north of the country. All of these identification processes can be implemented by using GIS mapping.

In terms of urban planning, there are three classifications of urban planning functions that use GIS as a tool, which are general administration, development control, and plan making. The use of GIS is according to functions, scales, sectors, and stages of urban planning. The statistical data shows that the use of the data management, visualization, spatial analysis, and modeling components of GIS vary according to different functions of urban planning (Nyerges *et al.*, 2011). Data management, mapping,

and spatial analysis are generally important in urban planning process and spatial modeling is used as strategic planning tools. General administration employs mainly data management and mapping. Finally, development control mostly uses the visualization and spatial analysis functions of GIS.

Materials and Parameters Selection

Commonly, 3D models have been used by various planning sectors such as city or urban planning, natural resource management, and transportation planning. With higher demand on application of GIS in industry and the need of proper visualization of 3D model, 3D modeling has evolved in producing more realistic models such as city landscapes with buildings, street furniture, and topographic variation. The 3D modeling for GIS data requires more analytical process in creating 3D model or 3D topology (Ellul *et al.*, 2013).

Traditionally, 3D physical models of landscape or mapping are generated or produced manually or by semimanual methods. The implication of this method is it consumes more time and manual effort to make a model that has high quality of visualization and precision according to the GIS data. It involves the use of cardboard sheet as material to build the 3D model. The cardboard sheets need to be cut and pasted on top of each other to produce a three-dimensional representation of topography. The geographical element can significantly be marked by using suitable common tools such as pushpins (point), colored string (lines), and paint (area). The advanced technology of 3D printing with the help from GIS data enables the 3D model to be rapidly built and can avoid delay to the business or operation due to 3D model production. Thus, it can speed up the process of negotiations especially during conflict resolution.

The GIS 3D model development is not to replace the paper maps or VR technique. It solves the visualization problem of current mapping method (2D) such as depth prediction, which can be resolved by a minor movement of the head or body. Other than that, the distance and height estimation become more effective and precise with 3D printing model due to lifelong experience with 3D views (Buchroithner, 2012).

The variation of printing parameters that involves printer setting parameters may influence the material properties, which will affect the reliability of the 3D part. The variation may alter the material properties, either making the material more durable or vice versa. There are several printing parameters that have been identified that may influence the material properties of printing material, which are the layer thickness, printing speed, printing and build orientation, and build infill of material.

The built layer of thickness can affect the material properties of tensile and flexural strength. It summarizes that, the 3D printing part, which made with thicker layer than each individual layer is capable to have high resistance against failure as compared with 3D printing part which is made with thinner layer. The “stepped effect” is suspected to affect the flexural and tensile strength, but it decreases with respect to the increase of layer thickness. Smaller layer height interlayer has strong bond strength. By decreasing layer height, more layers are needed to be printed for any given object. It yields benefits due to the layer can be reheated on the underlying bond lines. It promotes polymer diffusion and entanglement, which are caused by the increase of layer printing number (Abbott *et al.*, 2018).

The strength of 3D printing segment varies with the process parameter layer thickness. The smallest layer of thickness will have higher impact strength of the segment as compared with high layer thickness. This is because the small layer thickness provides the material with higher absorption of impact energy as compared with the part made with high layer thickness (Othman *et al.*, 2018).

Different built orientation of 3D printing can influence the quality of the printed product. Built material can react dissimilarly due to the relative position and the internal channel of the axial load, which depends on building orientation. The bond between layers is discovered to have only 74% to 79% of strength due to weaker bond between the layers. Built part that is constructed according to the X-direction (flat) has high strength and elongation before it achieves failure, and followed by the part that is built in the Y-direction and Z-direction (Raney *et al.*, 2017).

Polylactic acid (PLA) is a biodegradable 3D printing polymer material produced from renewable raw materials such as starch. Stereolithography and digital light processing 3D printing use PLA material in the form of resin while fused deposition method (FDM) 3D printing uses material in the form of filament. PLA material has lower performance of material properties as compared with acrylonitrile butadiene styrene (ABS), but it is available in several colors and is user friendly and to easy to handle in 3D printing. The extrusion temperature, which is also known as melting point of PLA, is around 180–230°C and the printing bed temperature is required to be controlled around 50–60°C. This range of parameters is beneficial in producing a high quality printed object or part. The PLA material is preferred to be used for printing of large parts because it has thermally less contractive properties. At high temperature process, PLA material does not emit toxic fumes and the installation of a fume hood becomes optional. Similar to ABS material, PLA material also has the characteristic to absorb moisture from ambient air and it affects the material properties and causes difficulties during the printing process.

Then, ABS is a commonly used 3D printing polymer material in varieties of application especially for FDM 3D printing. This because it is an inexpensive material and can be easily used by heating up the nozzle to a temperature to 250°C. The melting point of ABS materials is 230°C and the standard printing temperature is 230°C and above. ABS has excellent material properties such as strong, durable, partially flexible, and heat resistant, which makes it suitable for varieties of application. ABS material used for FDM 3D printing is usually in the filament form, which is available in various colors. Temperature of the printing bed needs to be controlled around 110°C for ABS material 3D printing. However, this type of polymer is not a biodegradable polymer but it can be recycled. Safety precautions are needed because ABS will produce harmful fumes when it undergoes high temperature processing. ABS also requires proper handling and storage because its performance can be degraded when it is exposed to sunlight for a long time. The printer performance can also be affected when it uses moisture ABS due to its properties to attract moisture from the air.

Research Methodology

There are two available standards in conducting Izod Impact Test, which are ASTM 256 and ISO 180. These standards focus on impact testing of notch specimen. The Izod impact test specimen sizes for ASTM 256 and ISO 180 are shown at Figs. 1 and 2, respectively.

Impact test is a mechanical test that is used to study the ability of material to resist impact loading by striking the tested material at high relative speed. There are two types of impact testing methods, which are pendulum and drop method. The pendulum method of impact test involves striking the specimen using an accelerated swinging pendulum. There are two types of pendulum method of impact test that are commonly used for plastic material testing, which are Charpy and Izod pendulum impact test. For Charpy impact test, the specimen is supported by a horizontal beam and it is broken at the line of impact between the supports by a single swing of a pendulum. The Izod impact test is similar to the Charpy impact test and the only difference is the position of the specimen, which is vertical against the striking pendulum. Another method of impact test is the drop method, which consists of two types: The falling dart and falling testing specimen method. The falling dart method involves striking the specimen with falling impact dart by gravity to determine its failure against falling impact, while the falling specimen method involves dropping the specimen at certain height to determine the material behavior when the impact is applied to the material.

By doing an impact test, the impact strength of a material can be determined. Impact strength is the material ability to sustain mechanical energy due to deformation and fracture under impact loading. It is also related to evaluating the material toughness, which is the ability of material to absorb energy by striking the specimen with pendulum. Theoretically, the material with high toughness has the ability to absorb higher amount of impact energy. Meanwhile, the low toughness material tends to absorb lower energy prior to fracture.

ASTM 256 standard is used to test plastic material in determining the resistance of plastic to standardized pendulum type hammers. The standard specimen is mounted in a standardized machine and breaks with one pendulum swing. This standard requires the specimen to be prepared accordingly. There are several types of test method that are stated in the standard. One of the methods requires the specimen to be held as a vertical cantilever beam and broken by single swing of pendulum. For the

Fig. 1 Schematic diagram of the specimen for Izod impact test ASTM 256.

Fig. 2 Schematic diagram of the specimen for Izod impact test ISO 180.

placement of the specimen on testing jig, the specimen line of initial contact is at fixed distance from the specimen clamp and from center line of the notch. The notch of the specimen will be facing the striker pendulum as shown in Fig. 3.

The striker of the pendulum is made from hardened steel type with cylindrical surface and can deliver 2.7 J. If the material requires more energy to break, additional load of the pendulum can be added. The testing procedure begins by placing the specimen at testing jig and the pendulum is pulled until it reaches 120°, which is measured by taking the location of specimen at zero location. The test needs to be conducted at standard temperature and condition, which are at 23°C and 50% relative humidity. The pendulum is released from its initial position when all parameters of the testing have been set up and the impact energy is recorded.

Results and Discussion

Impact test involves the study of material behavior against the impact loading, which in this case is focusing on dynamic loading effect on ABS and PLA material. Izod impact test is conducted to study the impact toughness, which is also known as impact strength of material. This approach has been used regularly for plastic material. Fifteen v-notch specimens of each material are prepared and tested to compare the impact strength between ABS and PLA materials. The impact specimens are fabricated according to ASTM 256 specimen size by using 3D printing method as shown in Fig. 4 for ABS and Fig. 5 for PLA. Even though the specimen notch is printed, an additional milling process is applied to make a notch of the specimen to have the desired notch

Abbreviations: ABS: acrylonitrile butadiene styrene; PLA: polylactic acid.

according to the standard. **Table 1** shows the impact test results for ABS and PLA materials and **Figs. 6** and **7** show the condition of specimens after the testing procedure.

In material behavior studies, method that is used to evaluate material toughness is the impact test. The theory of material toughness is related to the ductility and brittleness of a material. It can be explained by using stress–strain diagram to compare the differences between the ductile and brittle materials. The measurement of ductility and brittleness of material depends on the degree of plastic deformation that leads to material fracture, which is also known as the work done by material to fracture. Brittle material has small region of plastic deformation as compared with ductile material. The impact energy of material is the area under the stress–strain curve. Theoretically, material that has greater impact energy, which is ductile material, will have greater area under the stress–strain curve as compared with brittle material.

In impact test, there are four types of material fracture category, which are complete break, hinge break, partial break, and nonbreak fracture. The types of fracture must be recorded for the purpose of microstructure study regarding the material behavior. The notch specimen is used to enhance the sensitivity and reproducibility of the measurement, which serves as a stress concentration zone.

By doing impact testing on a material, the absorbed energy for the material to break or fracture can be determined to find the impact strength of the material. The absorbed energy that causes the material to break can be determined by hitting the material with high velocity impact pendulum. Absorbed energy is the amount of energy that can be absorbed by the specimen during the entire impact test procedure. It represents the energy to withstand maximum load when the specimen experiences failure at the maximum load point. In other words, it is the total impact energy that involves energy from initial and after impact. At the end of the impact test, the toughness of the material can be determined or compared by referring it to the impact strength of the material.

By making comparison between the impact test results of ABS and PLA materials, the correlation between both materials impact test results can be found. **Fig. 8** shows the values of impact strength for ABS and PLA materials. From the test, ABS material

Fig. 11 Polylactic acid material after impact test.

has higher value of impact strength with 11.63 kJ/m^2 as compared with PLA material with the value of 3.329 kJ/m^2 . This shows that ABS can resist higher impact than PLA material with 71.36% differences.

As seen in **Fig. 9**, all the ABS specimens show higher value of impact energy and impact strength than PLA material. Both materials can be categorized as polymer, which are classified as brittle material. From the theory of toughness, PLA material is more brittle than ABS material. This is because PLA material has a lower degree of plastic deformation as compared with ABS. The smaller region of plastic deformation for PLA material yields the effect of work done to the material until fracture. PLA material has lower work done to fracture, which is also known as modulus of toughness than ABS material. This because PLA material has lower

area under the stress–strain curve than ABS material. With this, PLA material only requires low absorbed energy for the material to fracture.

The other reason why PLA has lower impact strength as compared with ABS material is due to inconsistency or poor formation of first built layer of printing. As shown in [Fig. 10](#), PLA material shows poor formation of first layer of build as compared with ABS material. From the observation, PLA built filament, which is deposited as the first layer of build, does not consistently deposit, which causes the poor first layer of build. This affects the next layer of build if it is not deposited perfectly with other build layers. The poor deposited build material causes the formation of high intensity of air gaps and voids. The presence of air gaps and voids affect the strength of material against impact. Other than that, the higher intensity of voids and air gap has poor filling degree of built material and causes air inclusion between the printed strand. PLA material is suspected to have this kind of problem, which leads to very low impact strength. This is because the presence of high intensity of air gaps in the printed parts is responsible for weaker bonding between the built layer and printed filament, which causes the specimen to absorb low amount of energy required for complete fracture ([Santhakumar *et al.*, 2016](#)).

As shown in [Fig. 11](#), there are strands of filament that dissociate from the fractured specimen that can be observed after the test. It shows that the weak bonding between the built filament caused by the presence of voids and air gaps can affect the toughness of material.

Conclusion

Geospatial technology has been widely used nowadays due to its ability to provide geographical information and analysis effectively. It reaches the audience of the general public especially with the use of GPS in vehicle navigation devices. The use of geospatial technology in GIS has rapidly evolved especially with the introduction of 3D imaging. It provides the opportunity for topographical data to be visualized in mimicking the real conditions. 3D printing has been used to replace the manual method of using cardboard in producing these 3D images. One of the most-used approaches of 3D printing technique in topographical analysis is FDM. This article discusses the use of two types of FDM material that are commonly utilized, which are ABS and PLA. The impact behaviors of both materials are discussed in detail especially regarding the testing procedure and factor that contributing to the material's failure mode. From the experimental result, it shows that ABS material has greater impact performance than PLA and it is the preferred choice to be used in making 3D images of topographical data.

Introduction

In commercial applications TSE is one of the established processes for uniform blending of reinforcements in thermoplastic matrix resulting into improved morphology and mechanical properties of the composite prepared (Giles *et al.*, 2004). The reported studies based upon the destructive and non-destructive testing of thermoplastic composites with TSE have suggested significant improvement of polymeric composite properties (Agassant *et al.*, 2017). It has been observed that while using TSE for the feedstock filaments developments of fused deposition modeling (FDM) requires relatively high holding time for the heating and uniform mixing (Singh *et al.*, 2018a). But at the same time, overheating of materials in barrels should be minimized otherwise it may burn or degrade the mixture and can lead to losses of mechanical and morphological properties (Olahanmi *et al.*, 2016; Ray and Easteal, 2007; Chaitanya and Singh, 2017).

The FDM is one of the key processes for 3D printing of functional/nonfunctional prototypes, as it is capable of developing complex geometries in the short time. The rapid tools prepared by FDM have been applied in some studies for friction/friction stir welding and can be used for repair/maintenance purposes (Singh *et al.*, 2018b,c, 2016; Kumar *et al.*, 2018a,b,c). Conventionally friction stir welding (FSW) and friction stir processing (FSP) are the similar process but differentiated by the nature of application. FSW is techniques where a non-consumable tool of rotating type is inserted in between the interfaces of two sheets to create the diffusion of their edges for joining of materials, whereas FSP is considered as advancement for refinement of micro structural properties. For repair/maintenance of pipelines welding/joining of two similar material is quite common and various studies have been reported for joining of ABS-ABS, PA-PA, low density polyethylene (LDPE)-LDPE, high density polyethylene (HDPE)-HDPE etc. (Squeo *et al.*, 2009; Gonçalves *et al.*, 2015; Paoletti *et al.*, 2015). But when joining/welding of two dissimilar thermoplastic material was performed, it was not as simple to join/weld because both polymer exhibit different properties (e.g., melt flow index (MFI), melting point, molecular weight etc.) (Simões and Rodrigues, 2014; Oliveira *et al.*, 2010; Buffa *et al.*, 2016). After maintaining the MFI of two different polymers (ABS and PA6) by metal powder reinforcement in the close range, joining of dissimilar polymers was feasible (Kumar *et al.*, 2018d; Singh *et al.*, 2017a,b; Singh and Kumar, 2017; Kumar and Singh, 2018; Singh *et al.*, 2017c).

The literature survey reveals that in last two decades most of studies reported the approaches of FSSW by varying its input process parameters. But hitherto very little has been reported on the use of consumable tool for joining of thermoplastic composites sheets. In this study a framework of FSSW with the use of consumable pin as rapid tooling has been explored to be potentially applied it in maintenance and repair applications. The study demonstrates detailed methodology for use of TSE, FDM for melt flow compatible thermoplastic composite preparations and vertical milling setup for joining of Al reinforced ABS sheets with pin of Al reinforced PA6 as a case study.

Materials, Methods and Equipments Required

Fig. 1 shows the detailed methodology of TSE, FDM and FSSW processes for preparations of thermoplastic composites and joining with use of consumable pin profile. To conduct the experimentations, ABS (Grade - EX58) and PA6 (Grade - PX99848) thermoplastics of 1 mm granular size has been procured from the Batra polymers Pvt Ltd, India. Al powder as the reinforcement of 50 μ m size has been procured from Shiva chemical Pvt Ltd, Ludhiana, India.

The study is focused on the composite preparations and joining of substrates by using consumable tools. Following equipments have been used: MFI, TSE, FDM and vertical milling machine for FSSW process.

MFI

MFI of any thermoplastic composites is defined as the flow of materials from the nozzle of the MFI tester at standard temperature and loading conditions. For the present study the ASTM D 1238 standard has been used (Company: Shanta engineering, Pune, India, Model: 2013). The proportions of Al metal powder in the ABS and PA6 thermoplastic materials were varied from 0% to 50%.

TSE

For the extrusion of Al reinforced ABS and PA6 materials a TSE of co-rotating screws has been used (Company: Thermo scientific, Model: HAAKE MiniCTW). The TSE processing results into uniform mixing of the Al metal powder with ABS and PA6

Fig. 1 Detailed methodology for FSSW using consumable pin profile.

thermoplastic for preparation of feedstock filament with good control of dimensions. In the present case study, the feedstock filaments of 1.75 ± 0.05 mm size were prepared.

FDM

FDM is one of the low cost 3D printing techniques which is based upon the additive manufacturing concept. In this study, a commercial FDM printer (Company: Divide by Zero, India, Model: Accura 250Di) has been used for preparations of substrate and consumable pins of Al reinforced ABS and PA6 thermoplastic composites. FDM setup requires a .STL file format (stereo lithography) of 3D geometrical shape prepared on software. These geometrical .STL files are further mathematically oriented and sliced for desire prototype fabrication. The rectangular substrates of Al reinforced ABS and consumable pins of Al reinforced have been prepared under suggested processing conditions.

Vertical Milling Machine for FSSW Process

Fig. 2 shows the experimental setup for FSSW of Al reinforced ABS substrate by using consumable pins of Al reinforced PA6. The FDM printed samples were fixed on vertical milling setup with dynamometer arrangement (Make: Industrial engineering instrument, India, Model: Multi component digital force indicator, Model: 652) for FSSW. The thermal imaging camera was maintained at 500 mm distance with projectile angle of 60° . The measurement of axial and transverse forces has been taken to correlate it with the outcomes of the mechanical and morphological properties.

Experimentations

The rheological analysis reveals that ABS with 15% Al content and PA6 with 50% Al content results into MFI 11.57 g/10 min and 11.97 g/10 min respectively. Based upon these observations, ABS-15%Al and PA6-50%Al have been considered as the final

Fig. 2 Vertical milling setup equipped with thermal imaging and dynamometer for FSSW.

Table 1 Experimental condition for FSSW

Experiment no.	Rotational speed (rpm)	Plunge depth (mm)	Stirring time (s)
1	1200	2	15
2	1200	3	20
3	1200	4	10

composition for further experimentations. ABS-15%Al and PA6-50%Al were processed by TSE (Company: Thermo scientific, Model: HAAKE MiniCTW) for preparations of feedstock filaments. ABS-15%Al filaments was prepared at 220°C temperature, 30 rpm screw speed with 20 kg external load whereas feedstock filaments of PA6-50%Al was prepared at 245°C, 20 rpm screw speed with 15 kg external load. The levels of process variables were selected on the basis of pilot experimentations and it has been observed that uniform feedstock filaments were obtained only under these processing conditions.

3D printing of 60 × 60 × 4 mm sheets and 4 mm diameter pin by FDM was processed under infill percentage of 80%, filament diameter of 1.75 ± 0.05 mm, 6 perimeters, rectilinear filling, perimeter speed of 30 mm/s, printing speed 60 mm/s, extruder temperature of 250°C and printing bed at 55°C. Further FSSW was performed at 1200 rpm rotational speed of shoulder by varying the plunge depth (2–4 mm) and stirring time (10–20 s) for investigating the influences of process parameters (see [Table 1](#)). The range of selected levels of input process variables is dependent upon the feasibility of the FSSW process.

The mechanical (on universal tensile tester, Company: Shanta Engineering, Model: SE-500 kgf), thermal and morphological (by optical microscope, Model: XJL-17) properties FSSW welded parts were observed to investigate the influences of process parameters. ASTM D638 type IV (speed: 20/min) was followed for tensile properties evaluation and ASTM D 790 for flexural properties. ASTM E2015-04(2014) was followed for morphological analysis.

Results and Discussion

The joints were subjected to tensile, flexural, hardness and morphological testing, which shows that there is a significant variation of mechanical and morphological properties by varying the process parameters. The results are also supported by maximum interface temperature, maximum axial and transverse force which was observed during FSSW (see [Table 2](#)). It has been observed that maximum tensile strength at peak (91.1 MPa), maximum flexural strength at peak (66.90 MPa), maximum Shore D hardness (81.5 Shore D) and minimum percentage porosity at joints (13.09%) were obtained in experiment no. 3 (experimental conditions: 1200 rpm, plunge depth 4 mm and stirring time 10 mm) ([Table 2](#)). This may be due to the fact that maximum plunge depth and minimum stirring time contributed to more heat generations (71.0°C) and minimum force requirement (transverse force: 57 N and axial force: 120 N). In other words maximum plunge depth may have contributed for maximum heat generation so the joints prepared are uniformly stirred and free from porosity.

[Fig. 3](#) shows the thermal images of joints which were captured during FSSW process. It should be noted that maximum interfaced temperature was observed for sample 3 (671.0°C) and minimum for sample 2 (60.8°C). The sample 3 was processed

Table 2 Mechanical, morphological and online measured data for joining of ABS-15%Al substrate with consumable pin of PA6-50%Al

Experiment no.	Tensile strength at peak (MPa)	Flexural strength at peak (MPa)	Shore D hardness	Maximum interface temperature ($^{\circ}$ C)	Maximum axial force (N)	Maximum transverse force (N)	Percentage porosity at joints
1	89.2	66.90	79.0	66.4	145	60	14.58
2	72.4	61.0	78.0	60.8	170	55	13.58
3	91.1	66.90	81.5	71.0	120	57	13.09

**Fig. 3** Thermal images captured at different experimental conditions.**Fig. 4** Photomicrographs of FSSW joints at different experimental conditions.

with 4 mm depth of consumable pin which covers full thickness of ABS-15%Al substrate. The full length depth of pin profile resulted in the maximum heat generation which further contributed to maximizing mechanical strength.

Fig. 4 shows the photomicrographs of FSSW joints at different experimental conditions observed at 100 $\times$ magnifications. It should be noted that photomicrograph of sample 2 was obtained very rough and un-uniform with significance of un-mixed layers whereas photomicrograph of sample 3 has obtained with more stirred region and uniformly mixed surfaces.

Selecting the Optimum Process Parameters for Mechanical Properties

A surface plot for each mechanical property has been plotted to select the best set of process parameters. It should be noted from **Fig. 5(a–c)** that surface plot of tensile strength at peak, flexural strength at peak and Shore D hardness was elevated at 4 mm plunge depth and 10 s stirring time. So it is recommended that FSSW should be performed at 1200 rpm, under 10 s welding time with 4 mm depth of consumable pin.

Summary

The proposed route of FSSW for joining of 3D printed substrate by using consumable tools is recommended for use in repair and maintenance of cracked pipelines, and from mechanical strength view point, it has been observed that maximum tensile strength at peak (91.1 MPa), maximum flexural strength at peak (66.90 MPa), maximum Shore D hardness (81.5 Shore D) and minimum percentage porosity at joints (13.09%) were obtained in experiment no. 3 (experimental conditions: 1200 rpm, plunge depth 4 mm and stirring time 10 mm). It should be noted that maximum interfaced temperature was observed for sample 3 (71.0 $^{\circ}$ C) and minimum for sample 2 (60.8 $^{\circ}$ C). The sample 3 was processed with 4 mm depth of consumable pin which covers full thickness of ABS-15%Al substrate. The full length depth of pin profile resulted in the maximum heat generation which further contributed to maximizing mechanical strength. Based upon the analysis made for selecting the optimum set of process parameters, it is recommended that FSSW should be performed at 1200 rpm, under 10 s welding time with 4 mm depth of consumable pin.

Introduction

Conventionally, friction welding is a metalworking or forming process which is developed about 6 decades ago, is applied now in wide engineering fields such as: automobile, aviation, marine and oil industries (Kumar *et al.*, 2018a,b). Friction welding comes under solid state welding process which is basically performed under temperature below the melting points of parent materials (Kumar *et al.*, 2018c,d). The friction welding of metals, metallic alloys and composites, similar kind thermoplastic is quite common and it is adopted in real field applications due to sustainable joints formations (Abibe *et al.*, 2016; Oliveira *et al.*, 2010; Kumar *et al.*, 2018e; Singh *et al.*, 2019). But the friction welding of dissimilar thermoplastic or thermoplastic composite materials is still a challenging task because of difference in MFI, molecular weight, melting point, specific heat capacity, glass transition temperature etc. (Singh *et al.*, 2018a,b,c; Singh *et al.*, 2016). One of the reported alternatives for performing the friction welding of dissimilar thermoplastic (ABS and PA6) material is by maintaining similar MFI of those thermoplastics by reinforcement of metallic/nonmetallic particles in their matrix (Kumar *et al.*, 2017). Performance of friction based welding is dependent upon varying the input process variables and reinforcements (Kumar *et al.*, 2019). It has been reported that mechanical, thermal and metallurgical properties of solid state welded ABS joints were affected by level of vibration (Stokes and Hobbs, 1993). Study reported that interface properties like; fusion, deformation mechanisms and microstructure characteristics of friction welded interface are varied accordingly by rotational speed (Yilbas *et al.*, 1995; Yilmaz *et al.*, 2002). ABS and Nylon6 are commonly used thermoplastics with excellent mechanical properties and are used generally for friction welding application (Gao *et al.*, 2015). The joining of ABS or Nylon 6 to itself or welding of ABS to HDPE is feasible (Panneerselvam and Lenin, 2014). But, there is a limitation of joint strength (for friction welded joints) of these thermoplastics that hinders its use in different engineering applications. Friction stir welding (FSW) is one of the variants of solid-state joining/friction welding technique that uses a non-consumable tool to join two facing work pieces without melting the work piece material (Pabandi *et al.*, 2017).

Some studies suggested that reinforcement of metallic/nonmetallic particulates in thermoplastic matrix enhance basic material properties (thermal conductivity, MFI, specific heat capacities, melting points etc.) so the joints can be easily formed. But the gap has been found in ascertaining the role of heat generation on the mechanical strength of the welded joints. In the present study, 3D printed ABS and PA6 thermoplastic has been joined by friction welding on lathe setup under online interface temperature measuring by thermal imaging camera. Further analysis has been conducted to investigate the role of heat generation on mechanical properties of joints.

Materials and Methods

First of all pilot experimentation were conducted to check the feasibility for joining of ABS and PA6 on lathe setup by varying rotational speed from 5000–1500, feed rate of 0.045–0.18 mm/rev and actuating time of 2–20 s. It has been observed that joint obtained from friction welding of ABS and PA6 was weak and easily broken with small loading. The reason for weak joint may be related with wide difference in melt flow properties of ABS (MFI=8.76 g/10 min) and PA6 (MFI=23.27 g/10 min). So based upon these observations, a process chart has been developed to make feasible joints of ABS and PA6 by modifying their melt flow properties (see Fig. 1). Al metal particle (size: 50 μ m) were mechanically mixed into granules of ABS and PA6 matrix to investigate the MFI by varying its proportion from 0% to 50%.

It has been observed that MFI of ABS and PA6 thermoplastics resulted into similar MFI by incorporating 15% Al in ABS (MFI: 11.57 g/10 min for ABS-15Al) and 50% Al in PA6 (MFI: 11.97 g/10 min for PA6-50 Al). The feedstock filaments of ABS-15 Al were extruded by TSE setup under 220°C barrel temperature, 30 rpm screw speed with 20 kg load and PA6-50 Al under 245°C barrel temperature, 20 rpm Screw speed with 15 kg load (levels of parameters were selected as per pilot results). Further 3D printing (cylindrical surface: 50 mm diameter and 50 mm length) by using FDM has been performed for both thermoplastic composites under 30 mm/s printing speed, covering by 6 perimeters at 250°C temperature (see Fig. 2).

Further the mechanical, thermal and rheological properties of ABS-15 Al and PA6-50 Al have been checked as per ASTM standards (see Table 1).

Fig. 1 Methodology for joining of dissimilar thermoplastic based materials.

Fig. 2 Specimen (ABS-15 Al and PA6-50 Al) prepared by 3D printing for friction welding.

Table 1 Basic property of ABS-15 Al and PA6-50 Al

Materials	MFI (g/10 min)	Melting point (°C)	Break strength (MPa)	Peak strength (MPa)	Percentage elongation at break (%)	Percentage elongation at peak (%)
ABS-15 Al	11.57	203.20–223.59	202.07	224.30	12	11
PA6-50 Al	11.97	221.06	198.19	220.20	14	14

Experimentation

Based upon feasibility of joints formation, 3 different levels of rotational speed (500, 750 and 1200 rpm), welding actuation rate (0.045, 0.09 and 0.18 mm/s) and welding actuation time (4, 6 and 8 s) have been selected for final experimentation on lathe setup. The Taguchi L9 orthogonal array (O.A) approach has been employed for experimentation (see Table 2).

Fig. 3 shows photographs of joints obtained by friction welding.

Table 2 Design of experiment as per Taguchi L9 O.A

Experiment no.	Rotational speed (RPM)	Actuation rate (mm/rev)	Actuation time (s)
1	500	0.045	4
2	500	0.09	6
3	500	0.18	8
4	775	0.045	6
5	775	0.09	8
6	775	0.18	4
7	1200	0.045	8
8	1200	0.09	4
9	1200	0.18	6

Results and Discussion

Friction welding conducted by controlling rotational speed, actuation time and actuation rate with monitoring interface temperature. The joints were subjected to mechanical, morphological and thermal testing for investigating effects of process parameters.

Mechanical and Morphological Properties

It has been observed that maximum tensile and flexural strength (break and peak) and Shore D hardness were obtained at experiment no. 7 (parametric combination: 1200 rpm, 0.045 mm/min and 8 s) and minimum at experiment no. 3 (parametric combination: 500 rpm, 0.18 mm/min and 8 s) (see Table 3). The percentage porosity on joint surface may have contributed to weaker strength as largest porosity obtained for experiment no. 2. The porosity was lesser for sample of experiment no. 7 (exhibited maximum mechanical properties). The porosity on the joint surface may occurred due to improper mixing by insignificant heat generations.

Fig. 4 shows stress vs. strain curves of tensile properties. The maximum strength obtained for sample of experiment no. 7 whereas maximum elongation was observed for sample of experiment 8.

Fig. 5 shows stress vs. strain curves of flexural properties. The maximum strength obtained for sample of experiment no. 7 whereas maximum elongation was observed for sample of experiment 3.

Thermal Imaging

The interface temperature during friction welding is a measure of heat generation which promotes material flow. The material flow is an important aspect of welding process which ensures the soundness of the joints. In this study, the maximum temperature was measured for sample of experiment no. 7 (237.0°C) and minimum for experiment no. 3 (166.4°C) (see Fig. 6). It may occur due to a fact that higher rotational speed (1200 rpm) with lower actuation rate (0.045 mm/min) have contributed for better heat

Table 3 Mechanical and morphological properties of friction welded joints

Exp. no.	Tensile properties				Flexural properties				Shore D hardness	Porosity at joints (%)
	Strength at peak (MPa)	Strength at break (MPa)	% Elongation at peak	% Elongation at break	Strength at peak (kg/Sq mm)	Strength at break (kg/Sq mm)	% Deflection at peak	% Deflection at break		
1	63.3	57.0	7	7	159.7	143.7	5	8	79.0	17.25
2	56.0	50.4	6	6	150.0	135.0	2	3	78.5	22.24
3	30.7	27.6	4	7	123.2	110.9	8	13	77.0	25.47
4	91.6	82.5	9	9	270.1	243.1	3	3	80.5	15.45
5	83.1	74.8	8	9	247.4	222.6	6	6	80.0	16.05
6	71.9	64.7	6	6	160.9	144.8	7	7	79.5	16.67
7	102.5	92.2	8	8	300.4	270.3	3	3	82.5	12.57
8	100.5	90.5	10	12	255.7	230.1	5	7	81.5	13.05
9	90.7	81.6	8	9	197.4	177.7	4	4	81.0	14.57

**Fig. 4** Stress vs. strain curves for tensile properties.**Fig. 5** Stress vs. strain curves for flexural properties.

generation. Due to better heat generation material flow occurred better in case of sample of experiment no. 7 which promoted better material mixing (also minimized percentage porosity at joints). Similarly maximum porosity for sample of experiment no. 3 may occurred because improper material mixing promoted by insufficient heat generation.

Fig. 6 Thermal images of friction welding at different experimental conditions.

Photo-Micrographic Observations

The photomicrographs obtained at X30 magnification to investigate the joint morphology affected by varying process parameters (see Fig. 7). The joints of experiment no. 3 has obtained porous because of improper material mixing during joining. The porous structure was appeared as defect in the present study which minimizes the joints strength and joint hardness. On the other hand, the micrograph of experiment no. 7 has appeared more uniform and layer are uniformly mixed (it may occurred due to significant heat generation).

DSC

Samples of experiment no. 3 and 7 have been thermally tested by DSC equipment to investigate the role of input process variables. It should be noted that melting peak for sample of experiment no. 3 was obtained 218.85°C and for experiment no. 7 219.35°C (see Fig. 8). The more melting peak in case of sample of experiment no. 7 has paped due to fact that high rotational speed may

Fig. 7 Photomicrograph of joints interface at X30 magnification.

provided better material flow which made those material thermally more stable. This information can also be interpreted by normalized heat capacity rate as 26.21 J/g energy was required to melt the samples of experiment no. 3 whereas 58.50 J/g energy was required to melt the sample of experiment no. 7. The more heat required for melting indicates that more thermally stable is the materials.

Optimization of Process Parameters for Mechanical Properties

The signal to noise (SN) ratio of each property has been calculated to optimize the input process parameters. The mechanical properties (tensile, flexural and Shore D harness) were taken as 'larger is better' for calculating SN ratios (see [Table 4](#)).

[Fig. 9](#) shows main effect plot of SN ratio for mechanical and morphological properties. The mechanical properties were considered under 'larger is better' type case. The best setting obtained for each properties were also shown in [Table 7](#).

For optimization of each input process parameters as per variations over mechanical properties, a mathematical approach has been utilized as per results of SN ratio. [Table 5](#) shows analysis of variance (ANOVA) for SN ratios of peak strength (tensile). The rotational speed was contributed maximum whereas actuation time contributed least. Residual error was observed lesser than 5% shows acceptance of present model.

Fig. 8 DSC interpretation of sample of exp. 3 and exp. 7.

Table 4 SN ratio of mechanical and morphological properties

Exp no.	Tensile properties				Flexural properties				Shore D hardness
	Strength at peak	Strength at break	% Elongation at peak	% Elongation at break	Strength at peak	Strength at break	% Deflection at peak	% Deflection at break	
1	36.02	35.11	16.90	16.90	44.06	43.14	13.97	18.06	37.95
2	34.96	34.04	15.56	15.56	43.52	42.60	6.02	9.54	37.89
3	29.74	28.81	12.04	16.90	41.81	40.89	18.06	22.27	37.72
4	39.23	38.32	19.08	19.08	48.63	47.71	9.54	9.54	38.11
5	38.39	37.47	18.06	19.08	47.86	46.95	15.56	15.56	38.06
6	37.13	36.21	15.56	15.56	44.13	43.21	16.90	16.90	38.00
7	40.21	39.29	18.06	18.06	49.55	48.63	9.54	9.54	38.32
8	40.04	39.13	20.00	21.58	48.15	47.23	13.97	16.90	38.22
9	39.15	38.23	18.06	19.08	45.90	44.99	12.04	12.04	38.16

Table 6 shows response table SN ration for of peak strength. Rotational speed ranked 1, actuation rate ranked 2 and actuation time was ranked 3.

The optimum value of peak strength in tensile testing can be predicted by using following equation:

$$\eta_{opt} = m + (m_{A3} - m) + (m_{B1} - m) + (m_{C2} - m) \quad (1)$$

Where 'm' is the overall mean of SN ratio, m_{A3} is the mean of SN ratio for rotational speed at level 3, m_{B1} is the mean of SN ratio for actuation rate at level 1, and m_{C2} is the mean of SN data for actuation time at level 2.

Now for lesser is better by type case

$$y_{opt}^2 = (1/10)^{\eta_{opt}/10} \quad (2)$$

For properties, Larger is better type case

$$y_{opt}^2 = (10)^{\eta_{opt}/10} \quad (3)$$

Calculation:

Overall mean of SN ratio (m) was taken from Minitab software.

$m = 37.21$ dB (see Table 5)

Fig. 9 Linear model of SN ratios for different properties.

Now from response table of signal to noise ratio, $m_{A2} = 39.80$, $m_{B2} = 38.49$, $m_{C2} = 37.78$, (From [Table 6](#))

Now taking [Eq. \(1\)](#), putting the values

$$\eta_{\text{opt}} = 37.21 + (39.80 - 37.21) + (38.49 - 37.21) + (37.78 - 37.21)$$

$$\eta_{\text{opt}} = 41.65$$

Now, from [Eq. \(3\)](#) $y_{\text{opt}}^2 = (10)^{\eta_{\text{opt}}/10}$

$$y_{\text{opt}}^2 = (10)^{41.65/10}$$

$$y_{\text{opt}} = 120.92 \text{ MPa}$$

The predicted optimum value for peak strength in tensile testing = 120.92 MPa

Similarly this approach has been used to predict the optimum setting of each output parameters. [Table 7](#) shows predicted setting, predicted value and observed values of each output process parameters as per calculation made by [Tables 4–6](#).

Fig. 9 (Continued)

Fig. 10 Main effect plot for SN ratios of combined properties.

Conclusions

Following conclusions can be made from present study:

- The maximum tensile and flexural strength (break and peak) and Shore D hardness were obtained at experiment no. 7 (parametric combination: 1200 rpm, 0.045 mm/min and 8 s) and minimum at experiment no. 3 (parametric combination: 500 rpm, 0.18 mm/min and 8 s).
- Due to better heat generation material flow occurred better in case of sample of experiment no. 7 which promoted better material mixing (also minimized percentage porosity at joints).
- The joints of experiment no. 3 has obtained porous because of improper material mixing during joining. The porous structure was appeared as defect in the present study which minimizes the joints strength and joint hardness. On the other hand, the micrograph of experiment no. 7 has appeared more uniform and layer are uniformly mixed (it may occurred due to significant heat generation).
- This information can also be interpreted by normalized heat capacity rate as 26.21 J/g energy was required to melt the samples of experiment no. 3 whereas 58.50 J/g energy was required to melt the sample of experiment no. 7. The more heat required for melting indicates that more thermally stable is the materials.

Introduction

Friction welding (FW) was initially developed for similar metal/alloys welding, and later on it was also used for welding of thermoplastic composites (Taylor *et al.*, 1989; Yilbas *et al.*, 1995; Kostka *et al.*, 2009). The previous studies have reported for investigating the mechanical, thermal and metallurgical properties of friction welded surfaces (Gao *et al.*, 2015; Sluzalec, 1990; Stokes and Hobbs, 1993; Stokes, 1993). The interface properties at joints were examined to check the fusion, deformation and microstructure of friction welded surfaces by some researchers (Kostka *et al.*, 2009; Yilmaz *et al.*, 2002; Rotundo *et al.*, 2010). The acrylonitrile butadiene styrene (ABS) and nylon6 are commonly used thermoplastics having good range of mechanical, thermal, chemical, and morphological properties and are used in commercial FW application (Gao *et al.*, 2015). As per reported literature, joining of ABS with nylon 6 or joining of ABS to high-density polyethylene is possible with some iteration in rheological properties (like melt flow index (MFI)) for good mechanical strength (Panneerselvam and Lenin, 2014). However, joining of dissimilar material is limited because joint strength (for friction welded joints) is not up to the mark, which hinders its use in different engineering applications. Some of the studies have highlighted the use of a tool in the form of a ring that is rotated in between the interface of two pipes. This becomes heat deformed by friction created due to rotation of the ring, so welding of the pipeline is possible (Faes *et al.*, 2009). Friction inertia welding is widely accepted in aerospace applications (Attallah, 2012; Raab *et al.*, 2015). Reinforcement of polymer with nanocomposite can make the FW process feasible. The studies also highlight that friction spot welding of polymethyl-methacrylate and polymethyl-methacrylate-SiO₂ is feasible (Junior *et al.*, 2014a,b). The reinforcement of nanocomposite with polymers is responsible for the improved mechanical and metallurgical properties (D'Alvise *et al.*, 2002). The friction stir welding (FSW) process overcomes problem of void formation caused during FW. FSW requires a shoulder that is protruded with a pin called a probe. The shoulder arrangement creates the frictional heating and the pin probe facilitates stirring to the joint interface (Mohanty *et al.*, 2013). The FSW tool is one of the most important parts for success of the process. The tool consists of a rotary round shoulder and a threaded type of cylindrical pin (Thomas *et al.*, 1995; Dawes and Thomas, 1996; Nicholas and Thomas, 1998; Thomas *et al.*, 1999, 2003). Although prominent efforts have been made in previous years to develop economic and reusable tools, most of the attempts have been empirical in nature and further work is needed for refinement in tool geometry to modify the practice of FSW to hard metals and alloys (Rai *et al.*, 2011).

The reported studies for welding of dissimilar thermoplastic materials are limited with the use of different process variables and material variations. Some studies have reported the use of nanoparticulate for enhancing the joining compatibility of two different thermoplastic materials. Some authors have also reported the feasible joint formation after maintaining the MFI. The joints were subjected to tensile, flexural, and morphological analysis to investigate the influences of process parameters (Kumar *et al.*, 2019). However, no work has yet been reported on statistical analysis of the joints prepared by FSW process for batch production activities. The present work is an extension of work reported by Kumar *et al.* (2019) in which the FSW process has been employed for joining of ABS-15%Al with nylon6-50%Al from a statistical quality control (SQC) viewpoint.

Experimentation

Based upon the suggested methodology the ABS (Grade- EX58) and nylon6 (Grade- PX99848) thermoplastics along with Al metal powder have been selected for experimentation purposes (Kumar *et al.*, 2019). The mechanical mixing of thermoplastic with metal powder has been performed for uniform dispersion of metals into thermoplastic matrix. Further MFI of ABS with 15% Al content and nylon6 with 50% Al content were observed as 11.57 g/10 min and 11.97 g/10 min, respectively. So based upon similarity in MFI, ABS-15%Al and nylon6-50%Al have been considered as the final composition for further experiments. Twin screw extrusion and fused deposition modeling, as suggested in previous studies, were used for preparations of 60 × 60 × 4 mm sheets of ABS-15%Al and nylon6-50%Al (Kumar *et al.*, 2019). Fig. 1 shows the detailed procedure for the present experimental study.

Further the FSW of dissimilar sheets has been performed by using a nonconsumable pin profile of mild steel (see Fig. 2).

It has been reported that maximum joint strength in welding of ABS-15Al and PA6-50%Al was achieved at 1400 rpm rotational speed, 3 mm plunge depth, and 50 mm/min transverse speed (Kumar *et al.*, 2019). For establishing the proposed settings as industrial standards, the experiments were repeated at the proposed settings followed by SQC analysis (see Table 1).

Fig. 1 Steps involved for joining of dissimilar thermoplastic materials.

Fig. 2 Friction stir welding process for dissimilar thermoplastic joining. Reproduced from Kumar, R., Singh, R., Ahuja, I.P.S., 2019. Friction stir welding of ABS-15Al sheets by introducing compatible semi-consumable shoulder-less pin of PA6-50Al. Measurement 131, 461–472.

Fig. 5 X chart for shore D hardness.

Discussion

Based upon observations in [Table 1](#), X chart for peak tensile load, peak flexural load, and shore D hardness were plotted ([Figs. 3–5](#)).

As observed from [Figs. 3–5](#) the output parameters (tensile load, flexural load at peak, and shore hardness) are within the upper control limit and lower control limit, which have been judiciously selected based upon industrial applications. Since in the previous reported studies these output parameters have been maximized based upon analysis of variance data ([Kumar et al., 2019](#)), the 06 repetitions were made for SQC analysis. Further based upon [Table 1](#), process capability histogram and normal probability plot were drawn ([Figs. 6 and 7](#)) and Cp and Cpk values were computed ([Table 2](#)).

As shown in [Figs. 6 and 7](#) a well-defined bell-shaped curve with controlled deviation from mean value was observed. Further as shown in [Table 2](#), Cp and Cpk values are quite close to 1, thus ascertaining this process to be statistically controlled.

Fig. 6 Process capability histogram.

Summary

In the present study SQC analysis on a novel route for joining the dissimilar thermoplastic based composite materials by FSW for batch production has been reported. The X chart, Cp and Cpk values near to 1 ascertain that the proposed settings for this novel route are under statistical control and may be fixed as industrial standard for future references.

Introduction

Recently, the invention of synthetic rubbers is initiated to overcome the dependencies on the natural rubber due to the high demands of the rubber supplies. Consequently, it affects the demands of the natural rubber since the synthetic rubber offers better resistance to oils, temperature, and chemicals. Nevertheless, with specific compounding formulation, fillers additions and accurate manufacturing process enable the natural rubber to be continuously used in various applications such as vibration isolator and suspension system. The addition of fillers in the natural rubber compound can highly affect the properties and strength of the compounds, depending on the fillers types, sizes, and loading. Aside from that, it is also found that most of the projects in Malaysia prefer to use the imported rubber instead of the locally manufactured rubber, although it possesses comparable qualities.

On the other hand, based on previous research, it was found that the development of the suspension system for automotive mounting application is currently in trend (Salim *et al.*, 2013, 2014). Therefore, in this article, the application of Malaysian natural rubber, which is the vulcanized standard Malaysian rubber constant viscosity 60 (SMR CV-60) reinforced with carbon black (CB) as the potential main material is combined with the metal plate for the development of recyclable suspension system for different loading has become the interest. This article focuses on the investigation of the vulcanized SMR CV-60 mechanical properties through the transmissibility effect.

The development of recyclable suspension system for high-frequency protection application becomes the current research interest. Therefore, many agencies have taken an initiative to optimize the usage of local grade natural rubber instead of imported rubbers in the development of the suspension system by introducing SMR CV-60 as the main substance. Thus, in this article, the theories and the advantages of SMR CV-60 and ENR 25 are described. The importance of compounding ingredients and processing method in rubber compound are also explained. Besides that, the influence of carbon black in the natural rubber compound properties is also presented. The theories of transmissibility also literally presented in this article. Last but not least, the basic concept of the vibration isolation system, history and recent studies on the suspension system are also included to prove the effectiveness of natural rubber as the main substance of recyclable suspension system.

Carbon Black in Natural Rubbers

Nowadays, most of the rubber products used by customers especially in the anti-vibrating applications are reinforced with fillers. Different kind of fillers are available, however, only two types of fillers are known to reinforce rubber effectively, which are the CB and silica (Zhang *et al.*, 2001; Gent, 2012). Being easily available and inexpensive, both fillers are known to excellently improve the mechanical properties of the natural rubber in terms of tensile strength, elastic modulus, hardness, and hysteresis (Donnet, 2003). However, carbon black is frequently used as a filler in industrial applications as it is available in various sizes and easier to be produced. The effectiveness of carbon black over the other type of fillers as the reinforcing filler in the natural rubber compound has been proved through several studies (Ismail and Suryadiansyah, 2004; Ahmad *et al.*, 2016; Brum *et al.*, 2018).

In practical, the natural rubber is reinforced with carbon black for the purpose of providing extra strength for both raw and vulcanized rubbers at low manufacturing cost and at the same time to improve the rubber manufacturing process. The effect of carbon black in the natural rubber compound is highly depended on the chemical and physical interactions between the rubber matrix and fillers molecules. There are several factors that influence the interaction between the rubbers and carbon black molecules; the specific surface area, surface structure, particle size, and lastly the number of fillers loading.

The specific surface area and surface structure of carbon black influence the determination of rubber matrix chains and fillers entanglement level (Fröhlich *et al.*, 2005). The specific surface area of the carbon black is determined through its ability to absorb the cetyltrimethyl ammonium bromide (CTAB) in aqueous solution, as described in ASTM 3765. The CTAB unit is m^2/g . Filler with higher surface area, N472 for example, usually gives better reinforcement performance by having more available contact area to be bonded with rubber particles. On the other hand, the surface structure of carbon black is measured through the bulkiness of the carbon black aggregates and characterized by using its dibutylphthalate absorption number (DBPA) with the unit of $\text{cm}^3/100 \text{ g}$. Further explanation of the surface structure test method has been described in ASTM 2414. The bigger the carbon black aggregates, then the higher the carbon black structure. High carbon black structure increases the opportunity for carbon black to reinforce with rubber particle.

An investigation on the influence of carbon black structure towards the properties of the natural rubber compound by using FTIR and H-NMR has been conducted by Salaeh and Nakason (2012). Two types of carbon black with different

N800–N899	101–200
N900–N999	201–500

structure and surface are used: the high-abrasion furnace (HAF) and extra conductive furnace (ECF). Throughout the FTIR and H-NMR results, it is found that natural rubber with ECF-type CB exhibits good cure characteristics and mechanical properties which are Young's Modulus and hardness, respectively. Wide surface area and large surface structure in ECF encourage the entanglement between the rubber chain and carbon black molecule, increase the resistance of natural rubber compound towards the applied load. Meanwhile, in a study of material properties and fatigue life of natural rubber reinforced with different size of N-type of carbon black (N330, N990, N650), [Kim and Jeong \(2005\)](#) had found that natural rubber with N330 carbon black exhibited the highest hysteresis, small-scale roughness, and fatigue life cycle. The enhancement of natural rubber properties and fatigue life cycle is because of N330 has the largest specific surface area and surface structure as compared to N990 and N650. It causes the friction between rubber and carbon black particle to increase during the application of load, resulting the high hysteresis.

The next factor is the carbon particle size, which also influences the properties of the natural rubber compound. Particle with planar size (clay for example) has more contact probability with the rubber chain rather than the spherical size particle at similar average particle sizes such as carbon black and calcium carbonate. However, the smaller size of spherical size particle also gives better reinforcement performance as it appears as anisometric aggregates in per unit weight, which is small enough to make contact with the rubber chain. In contrast to the specific surface area factor, the reinforcing effects become more efficient as the particle size decreases; which the effective carbon particle sizes range from 20 nm to 50 nm ([Fröhlich et al., 2005](#)). Large particle size may contribute to the failure of rubber compound under the large stress such as stretching and flexing, especially when the particle size surpasses the inter-chain distance in the polymer itself. Smaller carbon particle also disperses evenly in rubber and agglomerates at moderate size, which is an additional factor for great rubber performance. [Rattanasom and Prasertsri \(2009\)](#) observed the effect of partial replacement of clay with three different grades of CB (N330, N550, and N774) on the vulcanized the natural rubber at similar hardness level. The authors found that the vulcanized natural rubber with N330 exhibited the highest edge-cut tensile strength, highest tensile and tear strength, and possessed the lowest resilient compared to the others. Notably, this occurrence is due to the great interaction between filler and rubber matrix, which resulting from good filler dispersion. The rubber chain is strongly linked on the carbon black surface, providing a good orientation of natural rubber chain along the applied force, thus gives more strength to the vulcanized natural rubber. The particle size of N-type carbon black (N is referring to the normal curing) ranges from semi reinforced to the highly reinforced is presented in [Table 1](#).

The last factor that influences the reinforcement of carbon black in natural rubber compound is the carbon loading. The high-performance polymer composite usually contains 50%–80% reinforcement particle by volume. The increase of carbon loading causes the inter-aggregate gap to become smaller, thus allowing the probability of rubber matrix filler network formation. [Ismail and Suryadiansyah \(2004\)](#) in their study on the effect of the carbon black loading (range from 0 to 30 wt%) in the polypropylene-natural rubber-recycle rubber composites had discovered the increase of stabilization torque value, tensile strength, and Young's Modulus in the composites with the increase of the carbon black loading. In addition, [Sangwichien et al. \(2008\)](#) in their study regarding the effect of various carbon black loading (ranged from 0 to 50 phr) on natural rubber or polypropylene composites also proved that the tensile strength increased as the carbon black loading was increased.

The carbon black used in this study was N330 carbon black, which was known to have good surface activity and chemical properties, which influenced the good interface interaction between the rubber chain and carbon black particle. However, the tensile strength value of the composites was found to slightly decrease for the compound with 50 phr of the carbon black. The excessive fillers content affected the processing characteristics and also the rubber compound crosslinking properties. As the carbon content was extended to a significant amount, the mechanical properties started to drop, which was attributed to the increase of viscosity in the matrix and in turn the increase in porosity and decrease in the wettability of the composites. The study also proved that the addition of the carbon black loading increased the hardness and reduced the tear strength, cure time and resilience values as well. In other research, [Fairuz et al. \(2016\)](#) also agreed that the increasing amount of filler loading will increase the tensile and flexural properties of the pultruded composites in terms of strength and stiffness. A study on the effect of clay loading on the natural rubber composite, conducted by [Mohd Nor and Othman \(2016\)](#) also agreed that the increase in filler loading will increase the curing characteristic and tensile properties in natural rubber composites.

Mechanical Testing for Rubbery Materials

Elastomer test is conducted to yield engineering design and quality control data for rubber compound. In mechanical testing for rubber compound, there are three classes of rate test procedure, which are the static test, dynamic test and quasi-static test methods. Besides, there are three types of testing within the three classes of rate test procedure, which are the tensile, compression and bending tests. Since this studies is only focusing on tensile and compression tests, only these two tests will be further discussed. The loading parameters to describe the elastomer behavior under mechanical loading are normally explained in term of stress and strain. Stress is defined as the force that acting on per unit area. The stress unit is often written in Pascal (Pa). The strain can be defined as the change in the dimension per unit length. The strain has no dimension. However, it can be written in cm/cm or mm/mm or in any equivalent dimension to measure the specimen length.

Tensile Test of Natural Rubber

Tensile test is considered as the fundamental test in mechanical testing. Even though it is hard to find the natural rubber application that involves the extension, but tensile properties are the most seek properties of the natural rubber compound after the hardness. The purpose of conducting this test is to ensure the quality of rubber compound for each production, in which occurs due to problems related to ingredients dispersion and insufficient vulcanization in compounds especially when reinforced with carbon black fillers (Dick, 2003). Besides that, the tensile properties are also used as the general measure to prove the rubber compound quality as the main substance in multiple applications (Sommer and Yeoh, 2012). Another advantage of the tensile test is several parameters can be obtained from a single test which is the stress, strain and modulus at specific elongation (normally at 100%, 300% and elongation at break).

Tensile test and properties are conducted and measured based on the guideline as stated in ASTM D412, which is the tensile test method for vulcanized thermosets rubbers and thermoplastic elastomers. This standard is referred for two different test methods: method A is for dumbbell and straight specimen and method B is for cut ring specimens. The specific shapes and sizes are also provided and can be chosen based on materials application.

Through the tensile test, there are several patterns of stress-strain curves that can be observed depending on the types of materials and the reinforcing fillers; as presented in Fig. 1. The curve in (a) exhibits a linear behavior starting from initial loading until rupture. It normally represents for brittle materials. Examples of brittle materials are ceramic, glass, and cast iron. Meanwhile, the nonlinear curves in b, c, & d represent the ductile materials with yield points (b & c) and without yield point (d). Examples of ductile materials are aluminum alloys, copper, mild steel and other metals. Unlike the other typical stress-strain curve, the elastomeric stress-strain curve as in (e) exhibits for a nonlinear "S" line with low stress and modulus at very high strains.

Several findings on the tensile test that had been conducted by previous researchers to determine the mechanical properties of rubbers at different types of fillers and loading were summarized in Table 2.

Compression Test on Natural Rubber

Compression test is used to determine the stress-strain behavior of materials under compressive loads. As compared to other tests of determining mechanical properties under axial loadings such as tensile and hardness tests, the compression test does not attain

the equivalence signification due to the relative irrelevance between the testing data and actual application measurement of the materials. Thus, the compression test is limited to the following applications; building construction, vibration isolation, fluid seal, suspension system and packaging.

In polymer, there are three ways that are usually considered in determining the compressibility in rubber compounds. Horgan and Murphy, 2009 classified compression test into three; which were the simple compression, volumetric, and hydrostatic compression tests. Simple compression was conducted by placing the cylindrical rubber between the compression platens unbounded, under compressive load. Meanwhile, the volumetric compression was conducted as the simple compression, somehow with rigid annulus. The rigid annulus was referred to the contact surface diameter of the rubber specimen with the unchanged platens while compressed. The hydrostatic compression test, which was also called as pure dilatation test involved a hydrostatic compression of the rubber samples.

As the compression test discloses the dependency of the materials under pressure, there are several things that might affect the compression test results. First is the ratio of the height to diameter of the specimen. High ratio value causes the buckling effect while low ratio value increases the friction rate between the specimen and compression plates. The ideal ratio is between 2 and 2.5 (Tscharnuter *et al.*, 2012). Secondly is the presence of friction between the sample and metal platen surface when the axial force is applied. The presence of friction restrains the rubber from expanding in a lateral direction under compressive force. Horgan and Murphy (2009) stated that the friction was unavoidable and could not be eliminated with the application of the lubrication. The authors also mentioned that even the smallest friction could significantly affect the measured stiffness and compression results either at low or high strain. Due to these factors, all compression results are measured by assuming zero friction and the compression data needs to be conducted with high precaution in order to minimize the friction effect.

According to the ASTM testing standard, there are two types of test method to measure the properties of NR under compression. First is the ASTM 395, which is the test method for the rubber that is subjected to the compressive stress in air or liquid. The significance of this test method is to measure the ability of the rubber to retain its elastics properties in response to the compressive stress. This test is also called as compression set test, which is frequently conducted under the influence of elevated temperature. This standard offers two options of the testing method, either by conducting the compression test under constant force or constant deflection. Secondly is the ASTM D575, which is the standard test method to measure the properties of rubber compound. This test method also offers two options of test method, which are the compression test of specified deflection or specified force. Both methods can be used to determine the compression-deflection and comparing the stiffness in the rubber compound.

A typical simple compression force-deflection curve that exhibits the loading and unloading phase is showed in Fig. 2. In compression properties measurement, the modulus of deformation can be derived from the compressive stress-strain curve (Auvray *et al.*, 2017). All findings that were related to the simple compression test that had been conducted by the previous researchers are presented in the Table 3.

Recyclable Suspension System Theory

Suspension system is installed in most of mega-structures such as high-rise buildings, nuclear reactor plants, bridges, and offshore jacket platform. The main purpose is to reduce the excessive vibration transmission from the sources of excitation from the base to the bodies or vice versa. A simple suspension system concept can be presented in a form of lumped element system, as shown in Fig. 3. The system consists of the mass, M , the isolation system (a spring, k and a damper, C) and the foundation. Basically, the

Fig. 3 Lumped parameter model for suspension system.

suspension system that consists of a spring and a damper act as an absorber to stop the oscillation in the system. It is located in between the source of excitation force, F_e , and the protected body. This system acts by weakening the transmitted vibration that larger than the excitation frequency, thus reducing the transmitted force, F_t to the protected body.

The lumped parameter model as shown above can be mathematically explained by using the equation of motion for a single degree of freedom system. There are several assumptions that is taken into consideration while deriving the equation: the mass of the block is negligible, only the vertical force is considered in the derivation and the force is assumed to be applied at a constant speed. Thus the general form of the equation of motion for the suspension system is derived in Eq. (1) as follows;

$$F_e(t) = M\ddot{y} + c\dot{y} + ky \quad (1)$$

where F , M , c , and k are the force, mass, viscous damping and stiffness matrices.

Meanwhile, the equation of the harmonic motion is written as Eq. (2) and derived into Eqs. (3), and (4), respectively.

$$y = Y_e^{j\omega t} \quad (2)$$

$$\dot{y} = j\omega Y_e^{j\omega t} \quad (3)$$

$$\ddot{y} = -\omega^2 Y_e^{j\omega t} \quad (4)$$

where Y is the amplitude and ω is the frequency.

Since the motion of the suspension system is assumed to be harmonic, the harmonic motion in Eqs. (2), (3) and (4) can be substituted into the equation of motion in Eq. (1). In general form, the equation is written as in Eq. (5) and simplified into Eq. (6).

$$F_e^{j\omega t} = M(-\omega^2 Y_e^{j\omega t}) + c(j\omega Y_e^{j\omega t}) + k(Y_e^{j\omega t}) \quad (5)$$

$$Y = \frac{F_e}{-\omega^2 M + \omega jc + k} \quad (6)$$

Thus, the excitation force equation is written by rearranging the Eq. (6) into Eq. (7).

$$F_e = Y(-\omega^2 M + \omega jc + k) \quad (7)$$

On the other hand, the equation of motion and the harmonic motion equation for the transmitted force to the foundation are derived as in Eqs. (8) and (9), which are

$$F_t(t) = c\dot{y} + ky \quad (8)$$

$$F_t = Y(\omega jc + k) \quad (9)$$

The performance of the vibration isolator is highly influenced by its characteristics and evaluated through the ratio of the transmitted force to the excitation force (F_t / F_e) that is known as transmissibility, TR . Measured in decibels units (dB) and assumed to be in the single degree of freedom, the transmissibility can be expressed in term of the differential equation of motion as in Eq. (10), which is

$$TR = \frac{F_t}{F_e} = \sqrt{\frac{1 + (2\xi r)^2}{(1-r^2)^2 + 2(\xi r)^2}} \quad (10)$$

where ξ is the damping ratio and r is the frequency ratio. The damping ratio and the frequency ratio are written as Eq. in (11) and (12), respectively.

$$\xi = \frac{c}{C_c} = \frac{c}{2M\omega_n} \quad (11)$$

$$r = \frac{\omega}{\omega_n} \quad (12)$$

where ω_n is the natural frequency of the suspension system and C_c is the critical damping. The natural frequency of the system can be calculated by using the Eq. (13) below.

$$\omega_n = \sqrt{\frac{k}{M}} \quad (13)$$

Fig. 4 shows the transmissibility curve in a system with different damping values. Based on the figure, it shows that the suspension system is acquired when frequency ratio is larger than 1.4 and the transmissibility increases with the increase of damping value. It is also found that the transmissibility peak reduces as the damping value is increased. In overall, it exposes of poor isolation at high frequency. Under those circumstances, it can be concluded that an ideal suspension system must possess:

- (1) Low natural frequency than the excitation frequency for effective suspension system due to isolation.
- (2) Low transmissibility in the amplification phase.
- (3) Rapid decrease of transmissibility at the frequency higher than natural frequency.

Fig. 4 The curve of transmissibility with different damping values.

Conclusion

This article elaborated mechanical and transmissibility effect on recyclable suspension system for different loading of carbon black. Some conclusion can be made which are the effectiveness of suspension system is based on the low natural frequency due to the isolation performance. Secondly, low transmissibility effect is only happening at amplification phase compare to the isolation region, and finally the transmissibility will drop when the frequency is increased.

Natural Oils as Green Lubricants in Forming Processes

Abdulaziz S Alaboodi, Qassim University, Buraydah, Saudi Arabia

© 2020 Elsevier Inc. All rights reserved.

Introduction

Animal and plant based oils have been used as a lubrication a long time ago. The petroleum discovery and following improvements in the technologies of refining replaced the oil based lubricant to the mineral oil based ones which is considered as an environmental pollutant. The total world energy consumption is estimated to be increased by about 33% during the period of 2010–2030, [Saidur et al. \(2011\)](#). The increasing global awareness of the health and environmental burdens connected using metal cutting fluids (mineral-based) in machining operations is forcing scientists and industrialists to seek for the development of new alternative, sustainable and environmentally friendly options such as nanoparticle suspended in vegetable oil. The characteristics of vegetable oils on respect of biodegradable, renewable and non-toxic make it the primary alternative for environmentally aspects. In addition to the wide range of its lubricant applications ranging from grease to hydraulic oils. The low thermal conductivity of cutting fluids necessitates that nanoparticles of carbide, oxide, non-metals, metal nitrides and Carbon Nano Tubes (CNT) are introduced into cutting fluids which increases the thermal conductivity of cutting fluids.

The employment of lubricants in metal forming processes provides desirable tribological conditions at the interface between tool and workpiece. Furthermore, it is important to increase the formability of material, increasing the tool life and reducing the energy consumption. The hazardous effects of mineral based lubricants led to more awareness and concerns towards the substantial a step forward replacing them with environmental friendly lubricant. The heat transfer coefficient subjected to lubricant is affected by various parameters, such as heat flux, mass flux, oil concentration, vapor quality, saturation temperature geometric configuration, transport properties and thermodynamic. The heat transfer performance could be increased or decreased by using lubricant depending on the oil concentration, surface tension and geometry. In general, the presence of lubricant in metal forming processes will decrease the heat transfer performance as a results of oil film deposition, [Wang et al. \(2012\)](#). Biodiesel industries is expected to rapidly grow worldwide in the coming years and information on biodiesel production, feedstock, and characteristics will be crucial than ever, [Issariyakul and Dalai \(2014\)](#).

The vegetable oils have performed satisfactorily in metal working applications and have shown promising performance as engine oils and greases. From survey, the selection of lubricant to be used in such application is based on price, performance, and then the environmental consideration. The selection would change either by reducing the cost of the biodiesel or with the legislative pressure to restrict using of petroleum based products, [Mannekote et al. \(2018\)](#). **Fig. 1.** shows the different lubricant state and their working temperature ranges, [Syahir et al. \(2017\)](#).

Forming Processes

Manufacturing processes consist of many types such as forming, machining, casting and non-conventional methods. Forming is a process that uses suitable stresses causing material plastic deformation to produce certain shapes. Metal is the main material used in forming processes. However, plastic can be formed too as a request for plastic based products market. The main forming processes methods are, Forging, Rolling Extrusion, Sheet metal working, Thread rolling Rotary swaging, Electromagnetic forming and Explosive forming. **Fig. 2** shows some examples of forming processes, [Hashmi \(2014\)](#).

Palm pressed fiber (PPF) is the biomass waste produced at the palm oil production. PPF oil is a promising source of lubricant. Researcher investigated PPF using pyrolysis experiments and estimate the functional and yield properties of the produced oil. The obtained PPF oil through pyrolysis process need to be tested as a lubricant by comparison with palm olein (PO). The test of lubricate used one of the metal forming processes which is the cold work drawing. During the metal forming process test, the utilize of PPF perform effectively as lubricants PO, [Hafis et al. \(2013\)](#). **Fig. 2** shows the decrees of tool die angle with the decrees of the forming load as a results die geometry and opening ratio of die-to-die. **Fig. 3** shows the different products yield (gaseous, oil and char) from exposing PPF at temperature of 450°C. The results show that the PPF oil product yields are relatively high values with the right temperature set during pyrolysis process, [Hafis et al. \(2013\)](#).

Friction Coefficient Estimation

A tribometer is a measurement instrument of tribological parameters, such as friction force, coefficient of friction and wear volume, between two contacting surfaces as in **Fig. 4**. The tribometer was used to measure the wear and friction at ambient conditions to study the utilize of phosphonium and imidazolium-based Lubricants. The ITeE-PIB Polish method for testing lubricants under deterioration conditions was setup with a four-ball tribotester to evaluate the deterioration load and capacity of load-carrying (poz) at extreme pressures (EP). The technique has confirmed to be sensitive to extreme-pressure additives. The

optical 3D-surface measurement system has been used to characterize the surface roughness of worn materials. The geometric parameters shown in Fig. 5 are used to estimate the friction coefficient through the compression tests.

The surface contact mechanics is the most influence on the viscosity level of lubricant. The higher viscosity leads to carry a higher load of the lubricant to enhance the anti-wear and antifricition ability of the interacting surfaces. Fig. 6 shows the formation of the type of Bowden-Tabor of a boundary film.

Fig. 6 The Bowden-Tabor type boundary film model. Reproduced from Amiril, S.A.S., Rahim, E.A., Syahrullail, S., 2017. A review on ionic liquids as sustainable lubricants in manufacturing and engineering: Recent research, performance, and applications *J. Clean. Prod.* 168, 1571–1589.

The multiphase lubricants and surface texture (additives in base oil) effect the wear and friction performance throughout sliding. To study the effect of multiphase lubricants which environmental friendly at the transfer layer creation throughout sliding against different surface textures. The grinding angle is influenced the coefficient of friction (COF) in addition to the transfer layer formation (TLF). The grinding angle can be minimized by utilizing an optimum concentration of additive such as graphene, [Siddaiah et al. \(2019\)](#).

One of the promising green lubricant additives are Halloysite clay nanotubes (HNTs). They are non-toxic, low-cost and naturally-occurring nanoparticles. Experimental results exhibited that 0.05 wt% HNTs delayed of deterioration initiation. Moreover, they increased the load-carrying and scuffing load endurance by $\sim 72\%$ and 50% respectively. Wear volume loss and coefficient of friction were both lowered by $\sim 70\%$, and surface roughness was decrease as result of the formation of a tribofilm. The enhanced lubrication provided by HNT lubricant additives may reduce the cost by reducing the energy consumption and increasing tool life, [Peña-Parás et al. \(2017\)](#).

Prominent Natural Oils

The degradable vegetable oil has good biodegradability, high viscosity index, non-toxicity, smaller relative change in viscosity with temperature, abundant resources and high yield. It would decrease lubricant pollution to the environment and handling cost. It has a higher molecule weight, boiling or flash point which relatedly decreases loss during gasifying and atomizing and liable to hydrolyze, [Steigerwald \(2005\)](#). The conventional metal working fluid provide fluid like "flood" in the work area then filtered and recirculated in the system.

Some studies show that a significant exudation phenomenon at 80°C for all oils tested using the bi-layers rheology technique and exudation analysis. The problem could overcome by using vegetable tung oil with specific highly reactive characteristic. The oil polymerisation by thermal activation without utilizing catalysts permitted it to avoid the exudation phenomenon by increasing oil viscosity. In contrast, the degree of exudation was greatly decreased when using pure tung oil from 8% to 1% .

In high-strength applications, there is an increasing attention to epoxidized vegetable oils (EVOs) because of their high epoxy equivalent weight (EEW). Perilla oil extracted from *Perilla frutescens* seeds (Non-edible), was used to produce sustainable green epoxy using Prilezhaev epoxidation reaction. Thermodynamic characteristics such as activation entropy, activation enthalpy and Gibbs' free energy of activation were evaluated for both oxirane ring cleavage reactions and epoxidation. All the thermodynamic characteristics were perceived to be higher for post-oxirane cleavage reaction compared to epoxidation reaction, [Bétron et al. \(2016\)](#). Fish wastes are a prominent resource of bio-lubricant. The fish waste potential for biofuel od bio-lubricant is a function of the size and location of the processing plant, characteristics of the fish waste and type of lubricant requirements, [Jayasinghe and Hawboldt \(2012\)](#).

Addition of Nanoparticles

Nanoparticles as lubricant additives afford a reduction in wear and friction of nanoparticle-containing lubricant formulations in addition to improve tribological performance of metal-forming tools. The small and effective lubricant additives in the preparation of the base stock leads to significant enhancements to the lubricants characteristics. The lubricant attributes such as tribological characteristics, anti-oxidation capability and thermal properties could be improved through selected additive, [Shahnazar et al. \(2016\)](#).

Researchers utilized different test to evaluate the coefficient of friction such as standard ring compression test. The test was utilized to estimate the efficiency of measured lubricants. Friction coefficient and deformation load was used to compare the performance of lubricants. The test shows that the enriched nano-lubricants with nanoparticles have more capability of the friction reduction than the conventional lubricants ([Zareh-Desari and Davoodi, 2016](#)).

The room temperature ionic liquids (RTILs) is one of new family that environmentally friendly and sustainable. It has been utilized as green sustainable fluids additives and as in plant-based avocado oil to enhanced the tribological characteristics. The coefficient of friction could be decreased by 68.88% and the wear volume could be decrease by 73.37% by adding a certain percentage mix of RTIL with avocado oil, [Reeves et al. \(2018\)](#).

Detonation nanodiamond (DND) particles are green carbon additive to motor oils. Researchers studied DND impact on the performance of lubricant and found a positive compositions and fuel economy in engine tests. DND-based nanolubricants must be carefully produced due to the abrasive nature of diamond to avoid increased wear of the friction surfaces. Furthermore, to obtain an advantages from the friction reduction of polished surfaces, [Ivanov and Shenderova \(2017\)](#).

The SiO_2 and CuO nanoparticles were distributed in rape seed and soybean oils in diverse concentrations and their lubrication attribute were compared with two conventional metal forming lubricants, solid lubricant of zinc phosphate plus sodium soap and CM202A press drawing oil.

Chemical Processing Lubricant Without Additive

Chemical modification of lubricant is required for certain applications to overcome its disadvantages such as substandard low temperature characteristics and oxidative stability., The bio-based lubricants can perform better than the conventional lubricants

with suitable base oil and additive packages preparation, Syahir *et al.* (2017). Mineral based lubricants are categorized as hazardous wastes because they contain high levels of toxic organic particles. The used lubricants had been reused to supplement the conventional energy sources. However, the process has low cost but it also has the high environmental risk (Jafari and Hassanpour, 2014).

Triazolidione (TAD) is a straightforward, additive-free, crosslinking and functionalization chemistry strategy used to enhance many plant oils. The TAD equimolar functionalization reactions monitored by Nuclear Magnetic Resonance (NMR) and Mass Spectrometry (MS) analysis. Researchers used a sequence of synthesized bifunctional TAD molecules which used for the chemical crosslinking of plant oils. The obtained plant oil-based foils polymer networks showing a better thermal property, Türlüç *et al.* (2015).

The application of vegetable oils as potential metal working fluids due to the high performance of these oils for wide range of materials and working conditions. Amongst the vegetable oils are sunflower, soybean and rapeseed which possess the relevant properties as a potential lubricant fluid, Shashidhara and Jayaram (2010). The full hydrogenation reaction of polyunsaturated FAMES into methyl stearate (MS) is an industrial feedstock for the metalworking or machining such as emulsifiers, surfactants, etc., Bouriazos *et al.* (2015). The epoxidation of oleic FAMES or methyl oleate high from vegetable oils was carried out in a one-pot reaction utilizing copper catalysts throughout cumene as oxygen carrier, Scotti *et al.* (2015).

The bio-lubricant Tri-esters of fatty acids with polyols can be prepared through direct esterification of different acids with the polyol in the existence of amorphous solid acid catalysts, Zaccheria *et al.* (2016).

Heat Transfer Parameters

The heat removing capacity into the cutting fluids enhanced due to higher thermal conductivity, increased surface area of the nanoparticles, streamline motion and lower Reynolds number, Aurich *et al.* (2014). The thermal conductivity of the suspension increased by almost 20%–30% with small addition of nanoparticles (1–5 vol%), Wang and Fan (2011).

Hot forging, rolling and stamping processes can permit sufficient plastic flow of workpiece for final products in its essential intricate form. One of the problem facing the hot rolling process is that the roll surface temperature has to remain below 600°C, while the workpiece must be heated to 800–1200°C. The temperature distribution of hot strip rolling shown in Fig. 7. The consequently abrasive wear and the severe surface oxidation occurs at the tool surface, potentially can embed into the end-products to produce a low surface quality with erroneous dimensions, Wan *et al.* (2016). Hot metalworking process comprises high temperature tribology. Using of inorganic polymers lubricants in such application need to be adjusted to satisfy high temperature in hot manufacturing operations. Borax-, polyphosphate- and silicate- additives are deliver the appropriate friction and wear properties, will help to minimize materials loss of the high temperature metalworking process, and increase surface quality from the standpoint of tribology. Polyphosphate salt additives is a lubricant can adapt to a high temperatures metalworking application. It is also a cost effective and very stable friction at the mating surfaces, Wan *et al.* (2016).

Fig. 7 The interface in hot metal rolling processes. Reproduced from Wan, S., Tieu, A.K., Xia, Y., *et al.*, 2016. An overview of inorganic polymer as potential lubricant additive for high temperature tribology. Tribol. Int. 102, 620–635.

Limitation of Bio-Lubricant

The increase use of plant oils, has to compete with the increasing demand for bioenergy, that could lead to unbalanced supply and demand and the increasing demand for food in the world, [Salimon et al. \(2012\)](#). The conventional lubricants are not environmental friendly resulting of accidental spillage, mishandling and leakage etc., attitude threat and serious concern. These vegetable oils and their respective derivatives are environmentally friendly and therefore can be chosen as an alternative to the harmful oils currently used as lubricant, [Suhane et al. \(2018\)](#).

Researchers found that the vegetable oils have limited range of viscosities. Low viscosity constrains utilizing such biolubricants in several industrial applications. Thus, nanoparticle additive must be added to the lubricant to enhance its performance. Among of the additive are ethylene-vinyl acetate copolymer (EVA) and ethyl cellulose (EC), [Quinchia et al. \(2014\)](#).

One of vegetable oils disadvantage is their limited oxidative stability. The study has been made to carry out the effect of oxidation on the tribological performance of few vegetable oils. Under controlled conditions inducing the oxidation method, the oil samples were subjected to accelerated ageing in a dark oven at different temperatures. The samples were analyzed for the variation of viscosity, peroxide number and percentage of free fatty acid, then compared with fresh oils samples. The results showed that, the ageing temperature has effect on the oxidation of oil samples as the increased free fatty acids. The low coefficient of friction observed using four ball test for oxidized oil samples was a results of soft iron soap formation having low resistance to shear, [Mannekote and Kailas \(2012\)](#).

The recent developments in the area of biodegradable synthetic is the ester base stocks for formulation of lubricants. The developed products applicable in metal working fluids, automotive transmission fluids, fire resistant hydraulic fluids, neat cutting oils, industrial gear oils and automotive gear lubricants, [Nagendramma and Kaul \(2012\)](#). The lesquerella field pennycress, meadowfoam and cuphea PSR-23 crop were compared with commodity vegetable oils for their fatty acid (FA) profiles, low temperature, lubricating (viscosity and wear), and oxidative stability properties. The crop oils with an antioxidant additive (1%–3%) were as oxidatively stable as current conventional petroleum oil by utilizing the rotating pressurized vessel oxidation test with times > 200 min using the 4-ball anti-wear test. The test showed best results for cuphea and pennycress, [Cermak et al. \(2013\)](#).

The amino acid surfactants are less toxic than traditional surfactants and had excellent interfacial properties, [Liu et al. \(2018\)](#). Tailor-made ionic liquids (IL) investigated for application as lubricants. The physical and chemical characteristics of IL, have shown more promising. The ionic liquids are applicable as neat lubricants or additives on dissimilar sliding pairs. It is an excellence potential replacement to the conventional lubricants in industrial applications in regards of environmental hazards, biodegradability issues and future prospects.

The solid-state lubricant graphene-zinc oxide is composite film was studied as a friction and wear reduction. The graphene-zinc oxide film is able to maintain its lubricating effects under extreme operating conditions including 450 m sliding distance and 15 N normal load. The optical and spectroscopic analysis followed by tribological testing of the formed wear scars reveal a persistent protective film. The tribological performance of this graphene-rich composite was excellent that because of the zinc oxide adhesion effect, [Fraccascia et al. \(2018\)](#). The green products should have close proximity with high Relative Comparative Advantage (RCA). The maximum proximity green products with high RCA will have the highest growth ([Fraccascia et al., 2018](#)).

The commercial vegetable-based fluid LB 2000 (not edible) was studied to quantify their lubri-cooling capacity in addition to the chemical and physical properties. canola and Cottonseed oils showed decent results, considering that they are non-polluting and non-toxic. Attrition or adhesion was the main wear mechanism met, regardless of the oil tested, [Araújo Junior et al. \(2017\)](#).

Conclusion

In conclusion, the natural oil lubricant was raised as an alternative to mineral based lubricant. The environmental, economic and technical sides are the most parameters that led to adopting such kind of lubricant. Technical deficiency of natural oil such as thermal parameters and durability could be resolve by adding some particulate additive.

Introduction

Conventional machining processes are always associated with heat generation, tool wear, energy consumption, surface and subsurface defects of the workpiece including surface roughness, residual stresses etc. All these problems can be reduced/eliminated by providing proper lubrication to the machining zone during the machining process. The cutting fluid reduces coefficient of friction at the chip-tool interface as well as at the tool-workpiece interface. This in-turn diminishes frictional forces at the two interfaces resulting in reduction of resultant force. At the same time, it also helps in removal of chips during machining and cooling down the cutting zone effectively. The most common and conventional method of the use of lubricant during machining is flooded lubrication technique in which the lubricant is allowed to impinge on the cutting zone in abundance. Flooded lubrication technique is associated with various economic and environmental issues. Abundant usage of lubricant increases manufacturing cost and causes dermatological and respiratory syndromes to the machinists. A large amount of fluid used in this technique is generally mixed with biocides to make it reusable. Biocides are detrimental to the environment. Disposing of cutting fluid is also a great ecological concern if it is non-biodegradable. That is why governmental rules are becoming stricter towards the use and disposal of cutting fluids. The best and ideal alternative is to perform dry machining where no harmful cutting fluid is used. However, dry machining is not feasible in most of the cases. Another alternative is to use natural vegetable oils. The most important property of these oils is that they are biodegradable. However, the problem is that they can be used only after mixing with various additives. The additives are mixed in the vegetable oils to make them suitable for the use as cutting fluids. Several blends of such cutting fluids are available in the market. Initially, the share of such lubricants was very low in the worldwide lubricant market, but now, the growth is anticipated at a very high rate annually.

Natural Oils as Metal Cutting Fluids

Conventional lubricants can be effectively replaced by natural oils in machining processes. In the recent years, the demand for green lubricants is increasing day by day because they are non-toxic, environment-friendly and readily biodegradable in nature along with having good lubricating properties. In some cases, vegetable oils, having high affinity to the mating surfaces, show better lubricating properties than that of the petroleum-based oils. These oils can be used as base oils in lubricants because they generally remain liquid at room temperature as well as they contain at least one ester as a functional group. Chemical properties of a natural oil affect its successful application in machining process. Adsorption property of a natural oil that makes it able to adsorb onto frictional surface and prevent their contact during machining process depends on interaction of functional groups of the oil with the surfaces. Properties which allow a lubricant to act as metal cutting fluid include its non-toxicity, biodegradability, high viscosity index, good lubricity (Mahadi *et al.*, 2017) and its ability to form a boundary lubricant through penetration into the mating surfaces during machining. By adding suitable additives, properties of a natural oil acting as base oil can be altered to make it suitable for acting as a lubricant in machining processes. There are three important factors on which performance of a lubricant depends namely, base oil, additives and formulation methodology as shown in Fig. 1. Vegetable oils, though costly, performed better than synthetic or mineral oils.

Low thermo-oxidative stability is a major issue encountered during the use of natural oils in metal cutting applications. Their stability can be improved either through esterification/transesterification process for modification of the carboxyl group or through the methods like selective hydrogenation, dimerization/oligomerization, formation of C–C and C–O bonds, metathesis or oxidation used for modifications of the fatty acid chain (Shashidhara and Jayaram, 2010).

Additives

Natural oil alone (without additives) cannot be used as a metal cutting fluid because it lacks various lubricating features. Lubricant's performance is improved with the addition of proper additives. Additives affect significantly the properties of tribofilms or boundary lubrication film. This surface protection film is developed between the mating surfaces by chemical changes on the surfaces which are influenced by these additives. Most commonly used additives are sulphur based, zinc based or phosphorus based.

Commonly used additives can be subdivided into following groups on the basis of their function:

1. Anti-wear additives (AW)
2. Extreme pressure additives (EP)
3. Anti-oxidants (AO)
4. Emulsifying agents (EA)
5. Biocides

Fig. 1 Natural oils as lubricants.

A protective molecular film is produced by the AW additives that adheres to the contacting friction surfaces. This adsorption may be chemical or physical. Some of the examples of AW additives are zinc dialkyl dithiophosphates (ZDDP), S-[2-(acetamido) thiazol-1-yl] dialkyl dithiocarbamates, Palm oil methyl ester (POME) and Dibutyl 3.5-di-t-butyl-hydroxy benzyl phosphate (DBP). The additives form polar head of the molecular layers, which are closely packed and arranged in a proper order to form the lubricating film. Extreme Pressure (EP) additives form layers of sulphides, chlorides or phosphates of iron through tribochemical reactions and protect the mating surfaces in EP conditions. Zinc-Dialkyl-Dithio-Phosphate (ZDDP) acts as EP additive. Butylated hydroxyl anisole (BHA), Butylated hydroxyl toluene (BHT), Mon-tert-butyl-hydroquinone (TBHQ), propyl gallate (PG) etc. are those additives that act as chain-breaking antioxidants. Zinc dithiophosphates (DTP) and Dithiocarbamates (DTC) are the examples of peroxide decomposer antioxidants.

In addition to these additives, emulsifying agents (EA) are also to be mixed to develop stable natural oil-in-water emulsion. Polyoxyethylene (20) sorbitan monopalmitate, polyoxyethylene (40) sorbitan tetraoleate, polyoxyethylene (20) sorbitan mono-stearate, Ethoxylated oleic acid ester are some common non-ionic EA.

Biocides and anti-corrosive agents are to be added as additives according to the requirement. Ethanolamine is a good example of anti-corrosive agent as it helps in stabilizing the emulsion too. Biocides generally belong to family of triazine derivative (triclosan). They restrict the growth of bacteria and fungus in the vegetable oil. Selection of the additives should be made intelligently and only those additives should be added, which are necessary for a particular application.

Properties of Natural Oils

Natural oils demonstrated similar or in some cases better machining performance than that of the conventional mineral oils. In some basic properties, natural oils are superior to mineral oils. As far as their application in machining is concerned, the most important property is the lubricity of the natural oil. Boundary lubrication is the dominant lubrication mechanism in the vegetable oils because of high polarity of the base oil due to which strong interaction occurs between the fluid and the mating surfaces during machining. They show good lubricating behavior during machining because of the development of a relatively tight and sticky oily layer due to the following two reasons:

1. Polar charge present in fatty acids of the oil draws the molecules of oil towards the metallic surface. These molecules do not flow out easily from the interacting surfaces.
2. Oxygen-containing functional groups are present in these oils. These groups also have an affinity towards metallic surfaces.

Table 1 Properties of vegetable oils as lubricants

<i>Advantages (required qualities of metal working fluids)</i>	<i>Disadvantages</i>
High biodegradability	Low thermal stability
Low pollution of the environment	Oxidative stability
Compatibility with additive	High freezing point
Low production cost	Poor corrosion protection
Wide production possibilities	
High flash point	
Low volatility	
High viscosity indices	
Low toxicity	

Note: Shashidhara, Y.M., Jayaram, S.R., 2010. 'Vegetable oils as a potential cutting fluid – An evolution'. Tribology International 43 (5–6), 1073–1081. doi:10.1016/j.triboint.2009.12.065.

The most basic component of a vegetable oil is a glycerol molecule. Triacylglycerides (triglycerides) are glycerol molecules consisting of three long-chain fatty acids. Hydroxyl groups are attached to the fatty acids through ester linkages. Long chains of fatty acids are polar in nature, which make them able to provide lubricant films of high strength. This film interacts strongly with metallic surfaces and reduces both friction and wear.

Viscosity of natural oils is substantially higher than that of the mineral oils. Therefore, natural oils generally provide stable boundary lubrications during machining when they are applied through flooded lubrication technique. Some researchers found that during application of Minimum Quantity Lubrication (MQL), fluids with low viscosity and high coefficient of friction are required to get good machining performance. The fluid provides lubrication and the compressed air provides cooling during MQL. Therefore, in order to use these fluids during MQL, natural oils having comparatively lower viscosity should be used so that the fluid can easily penetrate the cutting zone even in the mist condition. In view of that, water-based emulsion of the natural oil is a good remedy for MQL applications because an emulsion has low viscosity than that of the straight oils. Furthermore, an emulsion of the natural oil has good thermal conductivity and high specific heat.

Another important characteristic of the natural oils, which make them favorable to the metal cutting applications is their high flash point. During machining operations, high temperature occurs in the machining zone. An oil with high flash point reduces the risk of fire and smoke.

In addition, natural oils are environmentally safe, neither posing any harm to the environment nor hazardous to life. Non-toxicity, biodegradability, and environmentally sound characteristics make natural oils green lubricants. Some favorable and unfavorable properties of natural oils to act as machining lubricants are listed in [Table 1](#).

Application of Natural Oils in Machining Processes

Performance of natural oils developed for metal cutting operations was evaluated for different conventional machining processes. The works reported by various researchers working in the area of application of natural oils during machining processes are described in the following sections to showcase the broad knowledge of the available literature on the subject.

Turning

Turning is the most basic and conventional machining process in which workpiece rotates during machining. The turning performance can be improved through proper lubrication. Natural oils showed satisfactory performance when applied during turning of different materials. Generally, researchers developed few cutting fluids based on different natural oils and their performance characteristics were investigated in terms of different performance indices like tool wear, surface roughness, forces etc. When the effect of different cutting fluids during turning of hardened steel were looked into, it was concluded that emulsion without mineral oil performed better than dry cutting or cutting with emulsion containing mineral oil. This was attributed to the improved lubricating action of fluid without mineral oil due to the presence of grease in it. Generally, groundnut oil proved to be the best cutting fluid when compared with other vegetable oils like palm kernel, coconut oil and shear butter oil during turning of aluminum and Al-alloys. Using groundnut oil, lowest forces were observed for machining aluminum at all feeds and for copper at high feed. Palm kernel oil provided lowest forces for copper at low feeds only. Performance of coconut oil was found to be superior as compared to water-soluble mineral oil and straight cutting oil. Even during turning of stainless steel, coconut oil provides lower values of workpiece surface roughness and tool flank wear at low speeds as compared to water-soluble mineral oil and straight cutting oil. This was attributed to the viscosity of the coconut oil which lies in between the viscosities of the other two fluids. Coconut oil penetrated the interfaces easily during cutting and provided proper lubrication as well as cooling. High heat dissipating ability made the coconut oil advantageous for metal cutting applications. The effect of food-grade vegetable oil applied through MQL technique during turning of AISI 9310 steel, as shown in [Fig. 2](#) below, was investigated by [Khan et al. \(2009\)](#) and compared with the dry and flooded lubrication. The MQL with natural oil reduced the temperature in the machining zone, eliminated built-up edge, reduced flank wear and improved the MRR and workpiece surface finish.

Fig. 2 Schematic view of MQL unit. Reproduced from Khan, M.M.A.A., Mithu, M.A.H.H., Dhar, N.R., 2009. 'Effects of minimum quantity lubrication on turning AISI 9310 alloy steel using vegetable oil-based cutting fluid'. *Journal of Materials Processing Technology* 209 (15–16), 5573–5583. doi:10.1016/j.jmatprotec.2009.05.014.

Natural oils mixed with nano-fluids also outperformed conventional metal cutting fluids containing nano lubricants during turning of steels. MoS_2 , Al_2O_3 , graphite and boric acid powders are well known solid lubricants. Lower values of cutting temperatures, tool flank wear and surface roughness were obtained when coconut oil-based nanofluids were used as compared to SAE-40-based nanofluids. Suspension of very small amount of nanoboric acid into the natural oil was found to be the best alternative. Neem oil provided better cooling capacity than that of the Karanja oil during turning of mild steel. Better surface finish was obtained when neem oil was used. Canola-based cutting fluid consisting of extreme pressure (EP) additive showed best performance when compared with other fluids. However, the amount of the additives should be judiciously selected. According to Ozelik *et al.* (2011a), canola-based cutting fluid, consisting of 8% of EP, showed best performance when canola-based and sunflower-based cutting fluids were developed with the addition of 8% and 12% sulphur-based extreme pressure (EP) additive, respectively (Polartech XP 9018). Therefore, petroleum-based cutting fluids can be replaced with natural oils effectively. Application of natural oils containing nano-particles of solid lubricants through MQL technique is an effective method to improve the machinability of super alloys. A commercial natural oil (Coolube 2210^{EP}) containing Al_2O_3 in suspended form applied through MQL technique during turning of Inconel 600 alloy performed satisfactorily. Significant reduction was observed in surface roughness, cutting force and tool wear when 6 vol% nano-particles of Al_2O_3 mixed with the cutting fluid was applied through MQL as compared to dry and MQL without nano-particles (Vasu and Reddy, 2011). Non-edible vegetable oils like Pongam (*Pongamia pinnata*) and Jatropa (*Jatropha curcas*) can also be applied as natural oils after some modifications. When two thermoxidatively modified non-edible vegetable oils, Pongam (*Pongamia pinnata*) and Jatropa (*Jatropha curcas*) were applied through MQL technique during turning of AA 6061 steel, both of the natural oils offered better performance than the mineral oil but Jatropa-based fluids provided minimum cutting power followed by Pongam-based fluids and then mineral oil (Shashidhara and Jayaram, 2013). Lawal *et al.* (2014) developed oil-in-water emulsions using palm kernel and cottonseed oils as shown in Fig. 3 below for turning AISI 4340 steel. Both the fluids performed satisfactorily for reducing cutting forces and surface roughness.

Milling

Like turning, natural oils performed well when applied during milling of various ferrous and non-ferrous materials. Sunflower oil and canola oil with 8% extreme pressure additives gave better results as compared to commercial semi-synthetic cutting fluid as far

'Evaluation of vegetable and mineral oil-in-water emulsion cutting fluids in turning AISI 4340 steel with coated carbide tools'. *Journal of Cleaner Production* 66, 610–618. doi:10.1016/j.jclepro.2013.11.066.

Fig. 4 A schematic of the experimental setup to test emulsification of vegetable oil in water. Reproduced from Burton, G., Goo, C.S., Zhang, Y., Jun, M.B.G., 2014. 'Use of vegetable oil in water emulsion achieved through ultrasonic atomization as cutting fluids in micro-milling'. *Journal of Manufacturing Processes* 16 (3), 405–413. doi:10.1016/j.jmapro.2014.04.005.

as surface roughness and forces were concerned during milling of stainless steels. High viscosity of palm oil having a large amount of unsaturated fatty acid lead to the formation of high strength lubricating film acting as a boundary lubricant during flooded lubrication. Palm oil can be applied through flooded lubrication technique during milling of Al-matrix composite to get minimum forces as compared to coconut oil, sunflower oil, and soyabean oil. Natural oils applied through MQL technique is a good alternative in milling process too. When palm oil was applied through MQL technique during flat end milling of stainless steel by uncoated solid carbide tools, surface roughness was reduced even when the tool had worn out. Palm oil provided highest tool life as compared to fatty alcohol and dry cutting. Commercially available vegetable oil applied through MQL during milling of steel using solid carbide cutting tool provided higher tool life through proper selection of cutting parameters. Excessive use of emulsifying agents cannot be justified due to their negative financial and environmental effects. In a one-of-its-kind attempt, water-based emulsion of canola oil through ultrasonic atomization was developed by Burton *et al.* (2014) as shown in Fig. 4, which completely circumvents the use of additives and emulsifying agents. The cutting fluid showed similar or better machining performance than conventional fluid in terms of reduction in chip thickness, burr formation and peak-to-valley values of forces during micro-milling of Al and steel (Burton *et al.*, 2014).

Natural oils containing no antioxidant performed better than the oils mixed with antioxidants during MQL-assisted milling of non-ferrous alloys like Inconel. High oleic sunflower oil (with no antioxidant) is a better option when compared with sunflower oil, castor oil and commercially recycled oil investigated in terms of their tribo-rheological behavior and environmental

Fig. 5 SEM micrographs of the drilled holes: (a) Run 1 – Compressed air lubrication. (b) Run 4 – Nanofluid MQL with paraffin oil and 1 vol% of nano-diamond. (c) Run 7 – Nanofluid MQL with vegetable oil and 2 vol% of nanodiamond. Reproduced from Nam, J.S., Lee, P.H., Lee, S.W., 2011. 'Experimental characterization of micro-drilling process using nanofluid minimum quantity lubrication'. *International Journal of Machine Tools and Manufacture* 51 (7–8), 649–652. doi:10.1016/j.ijmachtools.2011.04.005.

soundness. High oleic sunflower oil (with no antioxidant) was recommended because of the improvement in the tool life and providing similar environmental impact as compared to commercially available canola oil. The improvement in the tool life was attributed to the combined effect of high friction coefficient and low viscosity of the cutting fluids (Pereira *et al.*, 2017).

Drilling

Vegetable-based cutting fluids reduced thrust force and increased tool life significantly during drilling of steels. Emulsions of natural oils developed by mixing additives along with one or two surfactants to the base oil showed good drilling performance. Examples of such fluids containing surfactants are crude sunflower oil containing Tween 80 as a surfactant, refined sunflower oil containing Tween 80 as a surfactant, and sunflower oil containing a mixture of Tween 80 and Peg 400 as surfactants. Natural oils containing nanoparticles of solid lubricants also showed superior performance when applied through MQL. Micro-drilling process was characterized by Nam *et al.* (2011) using pure MQL and nanofluid (containing diamond particles of diameter 30 nm) MQL formed through vegetable oil and paraffin oil and compared with compressed air (CA) lubrication. Drilling torque, thrust force and quality of the drilled holes shown in Fig. 5 below suggested improvement in the process when MQL nanofluid containing 2 vol% of nanoparticles were added in the vegetable oil or 1 vol% of nanoparticles were added in the paraffin oil (Nam *et al.*, 2011).

Palm oil is also a better alternative for high-speed drilling of non-ferrous alloys. It showed the ability to provide low wear rate when applied through MQL technique in high-speed drilling of Ti-alloy. Low wear rate was attributed to the lubricant layer formed on the sliding interfaces. Two reasons for the formation of this thick lubricant layer were the high viscosity of the palm oil and the fatty acids present in the palm oil having a long chain of carbon which reacted with metallic oxides. Sometimes, vegetable oil-based lubricant developed by mixing more than one surfactant outperformed the one that contains only one surfactant. It was found that canola oil containing two surfactants performed better than the one that contains only one surfactant. Similarly, water-based emulsion of refined sunflower-based cutting fluids are also a good alternative. Based on statistical analysis it was concluded that it gave better surface finish as compared to mineral and semi-synthetic cutting fluids. The emulsion formed with refined crude oil mixed with Tween 85 (20%) and Peg 400 (3%) as surfactants outperformed other fluids due to its better lubricating capabilities (Ozcelik *et al.*, 2011b). Mathematical models based on fuzzy logic and regression analysis were developed for thrust force and surface roughness during drilling of steel using natural oils. Canola oil based lubricant developed by mixing two surfactants outperformed the one that contains only one surfactant (Kuram and Ozcelik, 2013). Canola-based cutting fluid showed better lubricating properties when compared with different natural oils containing crude or refined sunflower oil. Therefore, when evaluated in terms of different drilling responses like wear of the drill bit, thrust force and workpiece surface roughness during drilling of steel with HSSE tool, canola-based cutting fluid demonstrated best performance. In order to get high material removal rate values during drilling of steel, Jatropha-based oil is a better option than Pongam and mineral oil.

Grinding

Various new environment-friendly cutting fluids were developed by researchers to get high lubrication ability and good performance during grinding process in terms of radial wheel wear, grinding forces, workpiece surface quality etc. The base oil used in the new cutting fluids was a natural oil. Natural oil was generally mixed with water, derivative of triasine as bactericide, composition of synthetic ester as anticorrosive agent and polyglycol of synthetic ester as an emulsifying agent to make it suitable for the proper grinding operation. This type of eco-friendly cutting fluid fulfilled all environmental requirements and showed reduced wheel wear, grinding forces, and surface roughness. This type of fluid performed satisfactorily during CBN grinding of hardened steels too. Utilization of used cooking oil lubricant for grinding application is also a cheap and comparable alternative. When

Fig. 6 Coefficient of friction and specific grinding energy for the nanoparticle jet MQL grinding experiment with four types of base oil. Reproduced from Zhang, Y., Li, C., Jia, D., Zhang, D., Zhang, X., 2015. 'Experimental evaluation of MoS₂ nanoparticles in jet MQL grinding with different types of vegetable oil as base oil'. *Journal of Cleaner Production* 87 (C), 930–940. doi:10.1016/j.jclepro.2014.10.027.

these fluids were applied during grinding of hardened materials (hardness > 60 HRC) with vitrified bonded CBN grinding wheel, such lubricants did not show any negative effect on quality of workpiece surface and performed well for reducing wheel wear as compared to commercially available vegetable-based and mineral-based lubricants. Nano-particles like MoS₂ provided optimum performance when mixed with different natural oils and applied to the grinding of different types of steels. Lubricating properties of the natural oils containing MoS₂ in sequence were soybean oil followed by rapeseed oil and palm oil when these three oils were compared. Performance of soybean oil mixed with MoS₂ nanoparticles applied with different lubricating conditions (like flooded lubrication, MQL etc.) during surface grinding of steel and ductile cast iron was superior. Both frictional losses and energy consumption were reduced due to the addition of nanoparticles in the natural oil applied through MQL technique. Zhang *et al.* (2015) prepared three different types of cutting fluids based on soybean oil, rapeseed oil and palm oil containing MoS₂ nanoparticles and applied with MQL technique during grinding of 45 steel. As compared to liquid paraffin, the natural oils performed well in terms of coefficient of friction and specific grinding energy value as shown in Fig. 6.

Research and Development Challenges in the Application of Natural Fluids in Machining

Most of the researchers claimed better machining performance of various natural fluids as compared to conventional cutting fluids. They stated the observed results without discussing the mechanism or the reasons for those observations. Deep-seated investigation must be performed to find the actual mechanism of the working of natural oils during machining of different materials with different fluids.

In order to use natural oils as metal working fluids, various additives are to be mixed. Toxic and hazardous additives must be avoided. Harmless additives must be identified and developed so that the industries producing cutting oils use these additives enhancing the usage of the natural oils in the market.

Emulsifying agents are not recommended to be used in the fluids because these elements are hazardous to human health and detrimental to the environment. A very little work has been reported on the development of water-based emulsion of natural oils without mixing emulsifying agents. The methods developed so far must be explored further for different natural oils.

Most of the research was performed on ferrous metals and Aluminum alloys. Application of natural oils during machining of super alloys must be examined extensively.

Optimization of the parameters of the natural oil working as metal working fluids must be performed through multi-objective optimization techniques for different machining processes. It will make the implementation of the best suited natural fluids to a particular machining process on the shop floor easy and effective.

Conclusion

Natural oils have shown great potential to act as green lubricants for machining processes. Conventional lubricants that have been used in metal cutting industries must be replaced by the natural oils. This task is unavoidable as far as environmental issues are concerned. Although natural oils in their crude form are not suitable for metal cutting industries, they perform well after proper modifications. Application of the natural oil-based cutting fluids through MQL is also a promising technique. The performance can further be improved by mixing nano-particles into the fluid. Intelligent usage of the techniques developed so far is based on the optimization of the parameters governing the properties of the fluid along with the machining parameters.

Introduction

Oil palm shell (OPS) is a key waste product generated after the extraction of oil from oil palm tree (Okpala, 1990; Okafor, 1988). Oil palm nut produces two types of oil, namely palm oil and kernel oil. These are extracted from outer and inner cores of the oil palm nut, respectively. After oil extraction, the inner core of the nut, known as palm kernel, has the potential to be used as concrete coarse aggregate. Covered by a hard endocarp, palm kernel shell is also known as oil palm shell (Pantzaris and Jaaffar, 2002). Malaysia has abundant cultivation of palm oil trees. According to Tripathi *et al.* (2015), 52% of the total palm oil in the world has been produced in Malaysia. In Malaysia, there are about 3.8 million hectares of oil palm tree being planted and the coverage area is expected to increase to 5 million hectares in the year 2020 (Alengaram *et al.*, 2013a; Gungat *et al.*, 2013). OPS is produced in large quantities by oil palm mills. Over 4 million tonnes of solid wastes are produced annually (Alengaram *et al.*, 2013a; Aslam *et al.*, 2016; Nagaratnam *et al.*, 2016). Since the demand for palm oil is increasing, the production of solid wastes by oil palm industry is expected to increase too. These waste materials, a component of which is OPS, are traditionally disposed of either through incineration by conventional process or in landfill (Rahman Sobuz *et al.*, 2014). These disposal methods are not only expensive but also have created many environmental issues. To minimize environmental impacts of handling and disposing these agricultural wastes, many researchers have been studying the potential of using OPS as replacement material in construction industry.

In the last three decades, extensive research has been carried out on using waste (OPS) as alternative aggregates for the production of lightweight concrete in South East Asia (Alengaram *et al.*, 2013a). OPS is generally a porous material with porosity of 37% (Okpala, 1990). The porous structure of OPS greatly reduces the density and also improves the thermal conductivity. As a result, cellular structure of OPS reduces the weight of concrete and provides better thermal insulation. The reduction in density of OPS concrete is about 20%–25% when compared to normal concrete (Shafigh *et al.*, 2010). Earlier, poor workability (with low slump value) of concrete using OPS was reported by several researchers (Okpala, 1990; Okafor, 1988; Mannan and Ganapathy, 2001) even though high water to cement ratio was used. This is due to the irregular flaky shaped shape of OPS which makes cement difficult to lubricate aggregates to achieve appropriate workability. However, desirable workability was observed with the incorporation of small amounts superplasticizer (Neville, 1995). Superplasticizer has been used in developing OPS concrete by subsequent researchers (Shafigh *et al.*, 2012; Mo *et al.*, 2016b; Serri *et al.*, 2015). Additionally, several researchers demonstrated that properly proportioned OPS concrete can achieve compressive strength above 30 MPa (Shafigh *et al.*, 2011, 2012; Farahani *et al.*, 2017).

The incorporation of OPS in concrete provides an opportunity for this solid waste material to be implemented in construction industry. It is environmentally friendly and sustainable in the long run. The following sections present the physical properties of OPS, its effects on fresh properties of concrete as well as the properties in the hardened state. It is observed that OPS has a high potential to be incorporated in concrete as alternative coarse aggregates.

Physical Properties of OPS

In general, the mechanical properties of OPS concrete are significantly dependent on the physical properties of OPS itself. The specific gravity of OPS reported by several researchers is in the range of 1.17–1.62. The specific gravity of OPS is obviously lower than that of normal weight aggregates and the typical particle size distribution of OPS is shown in Table 1. It is noted that the particle size distribution of OPS is in the range of 3–14 mm. The loose bulk density of OPS is the range of 500–600 kg/m³ while compacted bulk density is in the range of 600–740 kg/m³. The bulk density of OPS is generally influenced by its shape and size.

As for the shape of OPS aggregate, it could take the form of irregular flaky shape, angular, circular or polygonal, depending on the extraction method. Typical OPS aggregate is shown in Fig. 1. The surface texture of OPS remains fairly smooth on both sides. Rough and spiky attire can be observed at the broken part. The thickness of OPS varies from 0.15 to 8 mm.

OPS aggregate is composed of porous structure and hence it tends to have high water absorption. Depending on the oil palm tree species and OPS maturity age, the 24-h water absorption can vary from 14% to 33%. Table 1 shows the water absorption of OPS reported by several researchers.

Since OPS has lower specific gravity and bulk density, the density of OPS concrete commonly falls in the range of 1600–1900 kg/m³. However, smooth texture and irregular shape of OPS can cause poor bonding between aggregates and cement paste. The water absorption of normal weight aggregate is commonly reported as 0.5%–1%, which is extremely low when compared to OPS.

Table 1 Physical properties of OPS

Researcher	Specific gravity	Loose bulk density (kg/m ³)	Compacted bulk density (kg/m ³)	Water absorption (%)
Okpala (1990)	1.37	512	589	27.3
Jumaat <i>et al.</i> (2009)	1.37	566	620	23.8
Shafigh <i>et al.</i> (2016)	1.21	–	–	20
Gibigaye <i>et al.</i> (2017)	1.31	530	–	19.93
Farahani <i>et al.</i> (2017)	1.19	–	674	20.6

**Fig. 1** Oil palm shell aggregate.

Workability of OPS Concrete

Several researchers (Okpala, 1990; Okafor, 1988; Mannan and Ganapathy, 2001) reported poor workability (low slump value) of OPS concrete even though high water to cement ratio was used at the earlier age. The irregular flaky shaped shape and high water absorption of OPS caused poor workability. By incorporating small amount of superplasticizer, reasonable workability can be achieved (Neville, 1995). As such, superplasticizer is used in developing OPS concrete by subsequence researchers (Shafigh *et al.*, 2012; Mo *et al.*, 2016b; Serri *et al.*, 2015). Similar to normal concrete, the workability of normally vibrated OPS concrete improves with increasing of water to cement ratio. However, several researchers stated low slump value does not necessarily assure its compressive strength. Yew *et al.* (2014a) studied OPS concrete with different age of OPS ranging from 3 to 15 years and the influence of OPS aggregate size on workability and observed that the workability of OPS improved when older age OPS was used. However, the workability was degraded when maximum aggregate size decreased from 12.5 to 9.5mm and the explanation was attributed to the crushing processes which increases the shape irregularity of OPS which can prevent the concrete to achieve full compaction. Moreover, Farahani *et al.* (2017) reported that the inclusion of supplementary cementitious material (SCM) such as fly ash and silica fume can improve the workability of OPS concrete significantly.

Hardened Properties of OPS Concrete

Compressive Strength

Extensive research has been carried out on using waste (OPS) as alternative aggregates for the production of lightweight concrete in South East Asia (Alengaram *et al.*, 2013a). Much effort has been made to improve compressive strength of OPS concrete through research. It is noted that the mix proportion and curing condition have influence on compressive strength of OPS concrete. At earlier years, Abdullah (1984) designed OPS concrete with w/c ratio of 0.4 in accordance to ACI. The designated OPS concrete achieved cube compressive strength of 20 MPa. Okafor (1988) concluded that concrete with compressive strength above 30 MPa cannot be produced by using OPS as aggregates.

Several researchers studied the method to improve the compressive strength such as chemical treatment of OPS (Chai *et al.*, 2014) and curing condition (Mannan *et al.*, 2002; Shafigh *et al.*, 2012). Mannan *et al.* (2006) carried out pre-treatment to OPS aggregates by using concentrated borate, sodium dichromate, ferrous sulphate, cupric sulphate pentahydrate, acetic acid, slaked lime and polyvinyl alcohol (PVA) solutions. The authors noticed that the concrete with OPS pre-treated with PVA solution was able to improve the compressive strength by almost 40%, which was from 23.6 to 32.84 MPa. The authors explained that OPS pre-treated with PVA solution

was able to improve the adhesion bond between OPS and cement paste. However, it will not be economical to carry out pre-treatment to OPS aggregates for industrial use. Shafigh *et al.* (2012) studied the effect of curing conditions including continuous dry and moist skin conditions curing, no curing regime and initial water curing regimes of 2, 4 and 6 days on compressive strength. The sensitivity due to poor curing can be minimized by reducing the w/c ratio of OPS concrete. The authors explained that the water content in the pore of OPS can provide internal curing which gives rise to improved hydration and strength development. It can also minimize autogenous shrinkage and cracking and hence enhance strength.

Also, several researchers demonstrated that properly proportioned OPS concrete can achieve compressive strength above 30 MPa. Shafigh *et al.* (2011) successfully produced high strength OPS concrete with 28-day compressive strength of 42–48 MPa. Shafigh *et al.* (2012) also reported the compressive strength of 34–53 MPa in their studies. A more recent research by Farahani *et al.* (2017) showed that OPS concrete with compressive strength 28–40 MPa can be produced with binary and ternary blended cement.

Okpala (1990) stated that the compressive strength of OPS concrete is greatly dependent on the interface bonding aggregates and cement paste. Mannan and Ganapathy (2004) reported that the individual characteristics of OPS aggregate including strength, thickness and density are lower than those of granite aggregate. The authors stated that OPKS shape irregularity leads to poor bonding and hence lowers concrete compressive strength. The authors further explained that compressive strength relies on both the strength of the aggregate and cement paste and also depends on which one of these two fails first. Alengaram *et al.* (2011) observed that compressive strength of OPS concrete specimens that contained supplementary cementitious material was higher than those without supplementary cementitious material. The authors stated that the infilling of pores by the finer particle generally strengthens the bond between the OPS and the cement matrix in the interfacial transition zone (ITZ). The authors demonstrated that the mortar has filled in the empty pores in SEM analysis. It can be concluded that the compressive strength of OPS concrete is highly dependent on the bonding between binder and aggregates in ITZ.

Splitting Tensile Strength

One of the most important properties of OPS concrete is its tensile strength. It is particularly true in the application of flexural structural member, to resist the tensile stress so as to prevent severe buckling. Several researchers (Shafigh *et al.*, 2012; Farahani *et al.*, 2017; Shafigh *et al.*, 2016) reported that the splitting tensile strength is 6%–10% of its compressive strength. Alengaram *et al.* (2010) stated that weaker bond between aggregate matrix contributes to the lower tensile strength in OPS concrete when compared to normal aggregates concrete. Shafigh *et al.* (2012) compared the splitting tensile strength of normal concrete and OPS concrete. The authors reported that the ratio of tensile splitting to compressive strength of OPS concrete is generally lower than normal aggregate concrete by 28%. Shafigh *et al.* (2013) studied the effect of high volume fly ash on splitting tensile strength of OPS concrete and reported that although 10% of fly ash replacement can increase the compressive strength of OPS concrete by 3.6%, the splitting tensile strength decreased by 19.7%. The authors explained that the material quality of interfacial transition zone (ITZ) that is responsible for tensile strength is poor. In the later study of Shafigh *et al.* (2016), the authors reported that a high volume of fly ash replacement can significantly reduce its splitting tensile strength. Yew *et al.* (2015) studied different type of polypropylene fiber on the splitting tensile strength of OPS concrete. It was noticed that addition of polypropylene fiber has positive effect on splitting tensile strength of OPS concrete and it significantly improves when the replacement volume increases. Several researchers derived the equation relating splitting tensile strength of OPS concrete to its compressive strength as shown in Table 2. Some equations have the similar value of coefficient. These equations are derived in the form of

$$f_t = k f_{cu}^a$$

where k and a is the coefficient derived from experimental data.

Modulus of Elasticity

Elastic modulus is another key property that determines the deformation of structural element under flexure. The compressive strength of concrete is closely related to its compressive strength. However, research shows that OPS has negative effect on the elastic modulus since it contributes lower compressive strength in concrete. Yew *et al.* (2014b) studied the effect of heat treatment on the elastic modulus of OPS concrete. The authors reported that heat treatment has positive effect on elastic modulus and increases it by 8.4%. The use of suitable heat treatment technique brings about a significant improvement to the compressive

Table 2 Equations for splitting tensile strength

Researchers	Equation
Shafigh <i>et al.</i> (2012)	$f_t = 0.358 f_{cu}^{0.675}$
Shafigh <i>et al.</i> (2014b)	$f_t = 0.27 f_{cu}^{0.63}$
Farahani <i>et al.</i> (2017)	$f_t = 0.146 f_{cu}^{0.835}$
Shafigh <i>et al.</i> (2018)	$f_t = 0.14 f_{cu}^{0.85}$

strength as well as elastic modulus, due to the enhanced adhesion between OPS and the cement matrix. [Yew et al. \(2015\)](#) also studied the effect of polypropylene fiber on elastic modulus of OPS concrete. The authors reported all the elastic modulus is the range of 12–15.4 GPa. Improvements of elastic modulus by incorporating fiber are observed in their studies. Due to higher aspect ratio and geometry of fibers, the shrinkage cracks in the concrete have been arrested and therefore the strain induced under compression loading has been reduced. Subsequently, the elastic modulus is improved. [Shafigh et al. \(2018\)](#) studied effect of combination two different aggregates, which are OPS and expanded clay, on the elastic modulus. The authors noticed that when aggregate was substituted with OPS by 25% and 50%, the elastic modulus was reduced by 4.4 and 12.7%. The reduction of elastic modulus was attributed to the weaker interfacial transition zone of concrete containing OPS.

Permeability and Void Content

The concrete permeation property determines the durability of the concrete in service since the concrete with high penetrability is more vulnerable to the ingress of harmful substances. Hence, it is essential to study the permeability of OPS concrete. The concrete permeability is closely related to the pore or air void present in the concrete where the deleterious objects can travel through the pore to damage the concrete ([Basheer et al., 2001](#)). According to [Mo et al. \(2015\)](#), OPS concrete was found to possess lower permeability than normal concrete, after performing water absorption and sorptivity tests. SEM analysis showed that there were fewer micro-cracks present and formed in the interfacial transition zone of concrete due to the softer properties of OPS aggregates which eventually reduced the permeability of concrete. In addition, [Shafigh et al. \(2011\)](#) designed several mix proportions of OPS concrete and conducted water absorption test for each mix design. The water absorption of OPS concrete was found in the range of 3%–6% which was below 10% and was graded as good concrete.

The majority of the research showed that the use of OPS as coarse aggregate in concrete could increase the permeability of concrete to water. The initial surface absorption of OPS concrete was determined to be 12%–40% more than the normal concrete, indicating higher concrete permeability ([Mannan and Ganapathy, 2002](#)). It was explained in the literature that the OPS aggregates contained large amount of pore and possessed high capacity of absorption which caused the OPS concrete to absorb more water. Furthermore, the flaky irregular shapes of OPS aggregates affected negatively the OPS concrete in achieving full compaction, resulting in the formation of void in the concrete ([Mannan and Ganapathy, 2004](#)). Besides, [Khankhaje et al. \(2016\)](#) showed that the high permeable property of OPS is appropriately to be used in producing pervious concrete where water can travel through easily. This type of concrete could be used for flatwork application as the permeable concrete allowed rainwater to pass through. The results show that the concrete permeability increases as the amount of OPS included increases.

The increment of concrete permeability as a result of using OPS could be minimized by adding supplementary cementitious materials. For instance, [Mo et al. \(2016a\)](#) incorporated ground granulated blast furnace slag (GGBS) in OPS concrete. It was found the water absorption rate of OPS concrete with GGBS reduced at replacement level of 20%–60%. The GGBS enhanced the interfacial transition zone of the cement matrix and aggregate in the concrete by densifying the pore structure.

Shrinkage

Shrinkage of concrete occurs when there is change in volume of the concrete. The volume change is mainly attributed to the movement of water in concrete where the water may be lost as a result of evaporation from wet concrete (plastic shrinkage), drying of hardened concrete (drying shrinkage) or hydration process (autogenous shrinkage) in concrete ([Silva et al., 2015](#)). Cracks will form on the surface of hardened concrete due to shrinkage and this may ease the entrance of harmful objects. Drying shrinkage of OPS concrete was studied by [Shafigh et al. \(2014a\)](#). In the investigation, drying shrinkages of OPS concrete and expanded clay (EC) concrete were compared. It was found that the initial drying shrinkage value of OPS concrete was twice more than the EC concrete. The difference between the shrinkage of two concretes slightly decreased with time. The reason could be due to the OPS concrete possessed lower elastic modulus which exhibited higher drying shrinkage than the EC concrete.

[Mannan and Ganapathy \(2002\)](#) found the drying shrinkage of OPS concrete was 6% and 14% higher than the control concrete at the 28th and 90th day respectively. According to the authors, concrete made with lightweight aggregates generally exhibited approximately 50% more shrinkage than the normal weight concrete. Also, lightweight aggregate such as OPS have open textured and irregular surface which gives the concrete a higher shrinkage value. Another study showed that OPS concrete exhibited more shrinkage than conventional concrete ([Mo et al., 2016a](#)). The lower rigidity of OPS aggregates offered lesser restraint to the deformation caused by the shrinkage of concrete. The smooth curved surface of OPS aggregates also provided less resistance to shrinkage movement in the concrete. In the study, GGBS was introduced to improve concrete performance. However, the results showed that the incorporation of GGBS increased the concrete shrinkage. It was implied in the literature that GGBS slowed down the hydration process which allowed more time for free water to escape from the pores.

[Traore et al. \(2018\)](#) found that the average shrinkage deformation of OPS concrete was two times higher than the control concrete. This was mainly due to the lower elasticity of OPS aggregates which could not resist distortion of cement paste caused by shrinkage. In their study, the effect of OPS aggregates treatment on the concrete shrinkage was investigated, namely treatment with lime (CH), sodium silicate (SS), polyvinyl alcohol (PVA), heat (TH) and OPS saturation (SAT). The OPS concrete treated with SAT method was found to have the lowest shrinkage deformation. The authors implied that there was free water available in the treated OPS aggregates which maintained the internal humidity of concrete, thus reducing concrete shrinkage.

Thermal Conductivity

Thermal conductivity of concrete is essential to be examined because it determines the insulation ability of a building. Concrete thermal conductivity refers to the capability of the concrete to transfer heat through the material. Due to the popularity of using various waste materials such as OPS in concrete, thermal conductivity of concrete has become an attentive study by recent researchers (Misri *et al.*, 2018). Based on the experimental study conducted by Okpala (1990), thermal conductivity of OPS concrete was less than normal concrete and categorized as poor conductor. This was attributed to the high porosity of the OPS concrete where the air voids minimized the propagation of heat.

Alengaram *et al.* (2013b) used OPS aggregates to make foamed concretes and determined their thermal conductivity. It was shown that the OPS foamed concrete possessed approximately 56% lower thermal conductivity than the conventional brick. OPS aggregate was porous which contained large amount pores that could entrap air. Apart from that, the thermal conductivity of concrete depended on its density whereby thermal conductivity would decrease with the density. Another investigation made by Liu *et al.* (2014) showed that both foamed and non-foamed OPS concretes were having lower thermal conductivity than block and bricks. It was explained that the OPS foamed concrete had cellular microstructure which prevented the loss of heat. Also, as the air was poor in conducting heat, this had contributed to the lower heat conductivity in porous OPS concrete.

Furthermore, Serri *et al.* (2014) studied the influence of cement content on the thermal conductivity of OPS concrete. It was shown that the heat conductivity of OPS concrete increased when the cement content increased. When more cement was added, more C-S-H gels were formed as a result of hydration which filled up the concrete pores, thus providing more solid medium for heat transfer. In another study, it was found that the thermal conductivity of OPS concrete were approximately 50% lower than conventional concrete (Traore *et al.*, 2018). The low value could be attributed to the better insulating properties of OPS aggregates. The authors also discovered that the OPS aggregates treated with saturation method exhibited the lowest thermal conductivity. This was due to the extra porosity created as a result of OPS pre-wetting which increased the air contents that insulated the heat.

Future Applications and Challenge

In the past decades, significant research interest concentrated on oil palm shell (OPS), particularly in South East Asia, as it was abundantly generated as solid wastes from agricultural industry. The present study provides framework for further investigation of OPS concrete, in terms fresh properties, hardened properties and long term durability. The following statements are some recommendations for future application regarding OPS in concrete industry.

- Past research has shown that OPS is suitable to be used as coarse aggregates both in crushed and uncrushed states. However, no research has been done to crushed OPS to be used as fine aggregates for concrete production.
- Currently, all the mix designs of OPS concrete are based on ACI and trial and error method. The target slump value and compressive strength cannot be achieved by following ACI method. As such, the development of simple performance based guideline for proportioning OPS concrete mix design is required.
- It has been reported in literature that the production of high strength OPS concrete requires relatively large amount of cement. It will be more beneficial to develop OPS concrete as self-compacting concrete which eliminate the requirement of concrete vibration to compensate the cost of extra cement requirement.

Conclusions

OPS is easily available from oil palm plantations, particularly in Malaysia and Indonesia, and therefore can be extensively supplied. It has attracted interest in research field. Based on the literature review above, the following conclusions can be drawn:

- OPS has significant potential to be used as lightweight coarse aggregates in concrete production.
- The workability of OPS is relatively poor when it is fully replaced with coarse aggregates. Addition of superplasticizer is capable of improving the concrete workability. The inclusion of optimum supplementary cementitious material such as silica fume and fly ash can slightly improve the OPS concrete workability.
- The compressive strength of OPS is highly dependent on individual strength of OPS, and the bond between the OPS and the matrix in the interfacial transition zone. The pre-treatment of OPS by using can polyvinyl alcohol (PVA) solution can improve the compressive strength of concrete by 40%.
- The concrete made by OPS aggregates is highly permeable to water since the concrete contains more air void. However, incorporation of supplementary cementitious material such as GGBS is capable of reducing the concrete permeability as it can densify the concrete pore structure.
- Since the OPS aggregates are soft and having lower modulus of elasticity, the OPS concrete experiences higher deformation due to shrinkage. Yet, the treatment of OPS through saturation (SAT) method can reduce the shrinkage.
- The thermal conductivity of OPS concrete is lower than the conventional concrete. This is due to high porosity of OPS aggregates that can entrap air to insulate heat energy.

Introduction

The polymer waste is a form of solid waste with has high impacts on the environment (Takoungsakdakun and Pongstabodee, 2007). The reported studies highlights that annual consumption of polymers have increased up to 20 times in present time from few million tons in 1950–2004 and it is still increasing. There is no authentic estimation available on the total amount of plastic waste generated, however, it is estimated that 70% of total plastic consumption is discarded as a waste, thus approximately 5.6 million tons per annum (TPA) of plastic waste is generated in developing country like India, which is about 15,342 tons per day (TPD). A survey has been conducted to analyse demand break up of plastic by types (see Table 1).

As observed from Table 1, PVC/PP/HDPE/LDPE contributed more toward the consumption of plastic. Due to highly versatile in nature, lighter than competing materials and customized abilities, are the major reasons for their usage as a packaging material. Further the increase in polymeric waste, creating a pressure to limit its usage (Mølgaard, 1995).

Presently, the scenario has changed and polymer packaging material waste can be recycled by different processes/methods (i.e., primary, secondary, tertiary and quaternary) along with the various identification/separation techniques. Most of the polymer waste originated from post-consumer based plastic materials. The literature reported that, recycling of post consumed plastic materials; find new possibilities in the area of product development (Lei et al., 2007; Marzouk et al., 2007; James et al., 2007). Among these HDPE and LDPE are most commonly used plastic packaging materials in commodities. Recycling of these materials is the only possibility to manage polymeric waste.

The recycling consists of four tasks namely collection, separation, reprocessing and marketing (Mølgaard, 1995; Shen et al., 1999). Recycling of polymer requires less energy in comparison to production of same polymer from virgin material (Curlee and Das, 1991). Studies showed that, some recycled polymers has established a great market value in the field of composites (Muzzy, 2006), auto parts (Scheirs, 1998), soil reinforcement (Murray et al., 2000), artificial implants, healthcare applications, medical delivery systems, removal of bacteria and water desalination (Subramanian, 2000). Therefore recycling is a rising issue in recent years due to great use of plastic (Gondal and Siddiqui, 2007). The main reasons of this growth are strength, user-friendly design, fabrication capabilities and low density. Researchers have also reported various recycling techniques for the preparation of products like plastic lumber (Breslin et al., 1998), composites by reinforcing metallic/ceramic materials etc., (Singh and Singh, 2016). However, reinforcements in polymer material can be performed economically by the mechanical recycling (primary and secondary).

Polymeric Packaging Materials

Various polymers/plastic based materials are used in daily life and may be considered as a waste after use. Two basic categories of plastic are designated as thermosetting (long strands) and thermoplastic (short link) materials. The 6 main families of thermoplastics used as packaging material are: LDPE, HDPE, polypropylenes (PP), polystyrene (PS), polyethylene terephthalate (PET) and polyvinyl chloride (PVC). A part from above acrylonitrile butadiene styrene (ABS) is a strong material for making plastic bodies such as water purifier body, laptop body etc. Table 2 shows some of the applications of recycled/virgin thermoplastics.

Although, virgin plastics are easily available in the market and can be processed with conventional methods, but in terms of energy requirement these plastics are on the verge of elimination of fossil fuels. First, plastics can be regarded as a form of stored potential energy as each year, producing virgin plastics requires 4% of the world's oil production equivalent to 1.3 billion barrels a year (Kreiger et al., 2014). So, it is always advisable to reuse and recycle the plastic waste.

Note: Bakker, E.J., Rem, P.C., Fraunholz, N., 2009. Upgrading mixed polyolefin waste with magnetic density separation. *Waste Management* 29 (5), 1712–1717.

PVC is a universal polymer which can be processed into a wide variety of short-life or long-life products (Sadat-Shojai and Bakhshandeh, 2011). Among these major types of plastics, the consumption of PVC contributes to 12% of total demand. Global plastics production capacity of PVC was about 61 million tons in 2013 (Kou *et al.*, 2009). Rigid plasticized PVC is commonly used in pipes, window framing, floor coverings, roofing sheets, and cables; thereby it is discarded at a high rate (Janajreh *et al.*, 2015). HDPE is a better material than the LDPE; it is most widely used material. It takes 1.75 kg of petroleum to make 1 kg of HDPE. It is commonly recycled material. Earlier, there was a major recycling of LDPE (low density polyethylene) but it takes high energy requirement of making LDPE as

compare to HDPE (Hamad *et al.*, 2013). Another form of HDPE is available, called rHDPE (recycled HDPE), HDPEi completely came from industrial waste (Lu and Oza, 2013) and is easily available from post-consumer based products (bags, glass, cups, bottles) (Achilias *et al.*, 2009). It is basically composed of carbon and hydrogen atoms joined to form a high molecular weight product (Hamad *et al.*, 2013). Being linear chain material it has higher strength than LDPE. HDPE is used for various industrial applications (because of good mechanical properties) and emerging as a potential structural matrix (Jaggi *et al.*, 2014). Most of researchers dealt with the HDPE as it is easy to recycle and contribution of HDPE in home products or commodities is highest amongst others. So post-consumer based waste plastic is HDPE based. LDPE is very less used polymer in these days because of its manufacturing requirement and other properties constraint. LDPE requires extremely high pressures. This high-pressure polymerization creates polyethylene with many branches; the branches are created due to intermolecular and intra molecular chain transfer during polymerization. The utility of low-density polyethylene is limited due to the high number of branches leading to poor strength properties and requirement of extreme pressure condition for its production (Kumar *et al.*, 2011). The structure of this LDPE is less crystalline as compare to HDPE with little or no branching (Hamad *et al.*, 2013). Plastic bottles are usually made up of PET (Welle, 2011). Use of plastics as bottles is increasing throughout the world (Kalantar *et al.*, 2012). But recycling of materials based on PET is often very complex and it requires heavy machinery and high investment, so most of the recycler is not interested in recycling of plastic materials based on PET.

Recycled Polymeric Packaging Materials for Additive Manufacturing Applications

Extrusion techniques are commonly used for the processing of polymeric based composites, which accommodates agricultural raw materials, food, waste, meat, and leather, as well as other raw materials (Mikulionok and Radchenko, 2012). Presently, both single and twin screw extruder are available for the recycling of polymeric materials.

Case Study

Among various additive manufacturing technologies, Fused Deposition modeling (FDM) is one of extensively used process for modeling and prototyping applications (Boparai *et al.*, 2016). Singh *et al.* (2016a) reported use of commercial FDM setup (U-Print model, Stratsys, USA) for using recycled thermoplastics. The work mainly focused on the developing alternate feed stock filament (having reinforcement in various combinations/proportions of particle sizes of Al_2O_3 in waste Nylon-6). The effect of particle size on mechanical properties of developed filament has been recorded. The single particle size (SPS), which have particle size of 100 μm , double particle size (DPS) represents particle sizes 100 μm and 120 μm , in equal proportion (by weight) and triple particle size (TPS) consists of three particle sizes (100 μm , 120 μm and 150 μm) in equal proportion (by weight) were explored. Here, the main focus was on the enhancement of FDM domain by developing alternative feedstock filament, with tailor made properties. The recyclability of waste Nylon 6 was carried out for additive manufacturing applications. The selected proportions of Al_2O_3 and waste Nylon 6 along with melt flow index (MFI) values are tabulated in Table 3. The average of three experimental runs for MFI and mechanical properties were carried out. It should be noted that MFI is required to estimate the processing conditions of alternative feedstock filament in FDM. The standard/commercial material for FDM is ABS (P-430 grade). Therefore it is necessary that MFI value of alternative material should be equal to standard material, so that FDM can process the alternative material without making any change in its software and hardware. The feedstock filaments of selected compositions/proportions were fabricated on single screw extruder. The mechanical properties such as percentage elongation, Young's Modulus, yield stress etc. were determined according to ASTM D 638 standard on universal testing machine.

In another study, Singh *et al.* (2016b) collected waste of HDPE and LDPE from local market. The process started with the washing of polymer waste in order to remove the contaminants and dirt particles. After washing of polymer different samples of HDPE and LDPE were taken for the MFI testing. Further separate case studies for HDPE 100%, HDPE90%+10%Fe, LDPE 100% and LDPE 94%+6% Fe powder reinforcement have been reported. From this study it has been concluded that polymer waste mainly HDPE and LDPE can be successfully used for structural engineering applications by preparing filament wire with screw extrusion route along with the metal powder reinforcement. The mechanical properties like (peak elongation, break strength and shore D hardness) and metallurgical property like porosity can be controlled based upon specific application. In case of reinforced HDPE i.e., 90% HDPE and 10% Fe powder, the mechanical properties obtained were better.

Subsequently, Boparai and Singh (2017) investigated the wear properties of rapid tooling (RT) with nano scale fillers for grinding applications. The RT has been prepared by using bio compatible composite material (BCCM) feed stock filament (consisting of waste Nylon6 as a binder, reinforced with biocompatible nano scale Al_2O_3 particles) on fused deposition modeling (FDM) for the development of grinding wheel having customized wear resistant properties. A comparative study has been conducted under dry sliding conditions in order to realize the tribological characteristics of FDM printed RT of BCCM and commercially used acrylonitrile butadiene styrene (ABS) material. Finally, it was concluded that, the FDM printed RT of proposed BCCM feedstock filament are more suitable for grinding applications especially in clinical dentistry.

Boparai and Singh (2018) also highlighted the thermal characterization of ABS-Graphene blended three dimensional (3D) printed functional prototypes by fused deposition modeling (FDM) process. These functional prototypes have some applications as an electro-chemical energy storage device (EESD). Initially, the suitability of ABS-Graphene composite material for FDM applications has been examined by melt flow index (MFI) test. After establishing MFI, the feedstock filament for FDM has been prepared by an extrusion process. The fabricated filament has been used for printing 3D functional prototypes for printing of in-

house EESD. The differential scanning calorimeter (DSC) analysis was conducted to understand the effect on glass transition temperature with the inclusion of Graphene (Gr) particles. It has been observed that the reinforced Gr particles act as a thermal reservoir (sink) and enhances its thermal/electrical conductivity.

Summary and Outlook

Plastics have been one of the materials which entered every production sector of our lives such as automotive, packaging, aerospace, building, furniture, toys, clothing, medical etc. This is mainly attributed due to its versatility and relatively low cost. The serviceability of plastic products is limited and the use of plastic packaging materials in daily life makes a vast plastics waste stream that causes a serious environmental problem. Therefore, suitable waste management strategy is one of the important aspects for sustainable development. The reinforcement of fillers (metal, ceramics, fibers etc.) in recyclable polymeric packaging materials such as HDPE, LDPE, Nylon etc. not only minimize plastic waste but also makes the product economical. The reported case studies highlighted some of the fields for active research in additive manufacturing with recycled packaging material along with gaps that requires further attention.

Recycled Polypropylene-Nanoclay Composites – Mechanical Properties

Mohd H Othman, Tun Hussein Onn University of Malaysia, Johor, Malaysia

© 2020 Elsevier Inc. All rights reserved.

Introduction

Engineering materials were typically divided into several classification, such as polymer, metal, ceramics and composites. Polymer was chosen in many types of applications as a result of this material outstanding properties such as cost effective material, low density, and better at certain mechanical properties. Moreover this material is easy to be processed and recycled as well. After the polymer had been used, most of the waste shall be dumped in landfills. Microbes need long time to decomposition this material because most of the polymer is non-biodegradable. Since 1960, a dramatic growth has been informed, that polymer waste had increased not less than 13% of community solid waste stream. Hence, polymer recycling had triggered the researchers to study the effect and method of polymer recycling towards the economy and environment (Zare, 2013). To quote one example, a research had been carried out by mixing the recycled polypropylene with the virgin material and using Taguchi method as the technique for improve the quality of part that created (Mehat and Kamaruddin, 2011). Another approach of recycling also had been discovered, whereby the waste polymer can be recycled to valuable chemical feedstock through chemical recycling process. These feedstock can be used in refineries and petrochemical industries (Salmiaton and Garforth, 2011).

It is easy to recycle a pure polymer hence the properties and handling can be predicted easily. But currently, the growing consumption of polymer products creates the urge to combine polymer with fillers. Nanotechnology is expected to become the imperative technology in the current century. Hence, many researchers tried to develop the application of nanofillers in the polymers such as polypropylene nanoclay nanocomposites, whereby substantial enhancements of mechanical, thermal, optical and barrier properties were gained by using the nanofillers. More than that, the addition of the nanofiller could proliferate the interphase surface of the molecules in matrix, and apparent area to volume ratio as well (Zare, 2013).

Another main issue regarding the high interest towards nanocomposites is the difference between nanofillers and micro fillers. It was found that outstanding advances could be attained with low content of nanoclay, deprived of additional charge, increment of density or decreasing the light transmission properties of matrix. Nonetheless, recycling of these nanocomposites materials is not that easy. Further research had been studied and required, to determine the current status of polymer recycling in nanotechnology, specifically for polypropylene nanoclay, to lead more research to cover the manufacturing industry need and interest (Zare, 2013).

Therefore, this article was made specifically to deliberate details about the recycling of polypropylene nanoclay composites. After a brief introduction, explaining the effect of clay loading, preparation and the application of this material, a review of mechanical properties for this material and its recycled compound shall be elucidated. The final conclusion and the future trend will be also delivered at the end of this article.

Polypropylene-Nanoclay Composites: Clay Loading, Preparation, and Application

Typical nanocomposites materials strengthened their matrix with one or more nanomaterials with the purpose to improve mechanical, tribological, physical, and thermal properties. PPNC or polypropylene nanoclay nanocomposites usually promotes improvement in properties such as high modulus, increased strength and heat resistance, decrease gas permeability and flammability, and it gets a lot of attention because of it (Othman *et al.*, 2013).

Generally PPNC has better materials properties among the other virgin polymer, such as the increase of modulus, strength and heat resistance, even with smaller fraction of clay content could change the properties with various processing condition. According to a review, a PPCN containing 1 wt%, 3 wt%, 5 wt% and 7 wt% of nanoclay have been studied before, and it was found that the tensile strength of PPCN had expanded proportional to the expanding in nanoclay content from 0 to 5 % of weight. As for composite with content more than 5 % weight, there is no significant improvement. The findings continued with dynamic mechanical analysis, with the results show that higher progression of modulus was obtained within the research's temperature range. Most nanocomposites which contained nanoclay also reducing the flammability behavior of the material, and the heat release rate as well. The main issue before utilizing this material in manufacturing industry is the preparation method to blend the polymer and nanoclay. The in situ intercalative polymerization and polymer solution intercalation will utilized the solvent, and melt intercalation was used by using twin screw extruder. Each method has its advantages and disadvantages to produce PPNC with good quality. However, melt intercalation was preferred as the standard in producing PPNC (Othman *et al.*, 2014). Moreover, higher melt strength and viscosity could be attained by using twin screw compounder during this preparation method, but certain provision need to be scrutinized in term of discrepancy of material dimension after leaving the die. This problem is critical in producing sheets or profiles shapes (Hamzehlou and Katbab, 2007).

In melt intercalation, there are several processes involve in this technique, such as annealing, and heat the mixtures of polypropylene and nanoclay to the melt point. In annealing the polymer chains of bulk polymer melt is mixed into the galleries between the silicate layers in annealing process. The polymer chain penetration rate into silicate galleries influence the various

nanocomposites with structures from intercalated to exfoliated that can be obtained. The experimental results show that polymer intercalation results are highly depend on the function of silicates and their constituent interactions. This technique has big advantages over in situ intercalative polymerization and polymer solution intercalation as this method is nonthreatening to the environment due to the absence of organic solvents. Moreover, injection molding method is very useful in the business, this method can create extensive amount of plastic products and furthermore can spare the time and the cost to make the product, and now more of plastic industries use injection molding method (Othman *et al.*, 2014).

During preparation of these nanocomposites, the amount of clay also plays a major role in affecting the properties of PPNC. For example, increasing the clay content in with a well-dispersed two-component system, can cause the impact strength to decrease while the crystallization kinetics and the spherulite size remained almost the same. On the other hand, an intercalated three-component system containing some dispersed clay as well as the clay tactoid, showed a much smaller size of spherulites and a slight increase in impact strength with increasing the clay content (Svoboda *et al.*, 2002).

Generally the main advantage of PPNC is this material is a lightweight material and more economical when compare with other material. It also very competitive with other commodity plastics that already exist in some applications. This material can be used in many part of automotive and food packaging industries. Henceforth, with the good mechanical properties improvement, ease in preparation the material and simple processes, the recycling process for this material could open the gate of a new era for plastic and composites (Sinha Ray and Okamoto, 2003).

Recycling of Polypropylene-Nanoclay

Until today, waste polymer treatment still working hard to increase their efficiency. Combustion and land fill are the last choice, because it is not environmental friendly. Hence, recycling will be the preferred option. Many method of recycling can be considered such as primary, mechanical, chemical or feedstock recycling and energy recovery as well (Sadat-Shojai and Bakhshandeh, 2010). According to a data, in year 2015, it is not more than 9.1 % of recycling rate achieved for the recycled plastic, which is relatively insignificant (see “Relevant Websites section”). The main reason of plastic’s low recycling rate is the separation process (Burat *et al.*, 2009). Plastics can be separated by the numerical coding system according to The ASTM International Resin Identification Coding System (ASTM D7611/D7611M-18, 2018). Other than separation process, another reason is the degradation of polymer structure, which can caused the decrease of properties (Goto *et al.*, 2006). To overcome these limitations, it seems that the easiest way to recycle the waste plastics is by utilizing the development of blends and composites from recycle materials.

Most of polymer especially polyolefins could be recycled. However, the most important factor of recycling process is cost and difficulty, whereby these factors needs to be reduced for economical reason. The recycling has several process such as sorting, collecting, cleaning and reprocessing. Recycling process for polypropylene begin by separating polypropylene with other plastic polymers to allow for recycling. Separation is obtained from the sink-float method, it works by distinguishing polypropylene density with other polymers, polypropylene will float and not with other material. Polypropylene has specific density of 0.93–0.95 g/cm³, polypropylene must also be separated by color before processing. If polypropylene is uniform, it will be shredded or chopped into pieces that can be sold again into recycled feedstock. Polypropylene can be further processed, mixed with other materials to produce a solid plastic pellet with an extruder (Thomas, 2012).

However, when the polypropylene matrix was been mixed with certain filler, the recycling process will be slightly different, as well as the outcomes. For instance, a research had been carried out regarding the preparation and characterization of recycled polypropylene that had been used as the matrix for nanocomposites. Based on the findings, it was found that the nanocomposite of recycled polypropylene and Cloisite 15A nanoclay had provided the highest improvement in mechanical properties, compared with other prepared samples. This research also designates the important of clay loading, compatibilizer and the processing parameter as well (Cengiz, 2008).

More research had been performed about the recycling process of polypropylene and the mechanical properties of recycled polypropylene/organoclay nanocomposites. Based on the researcher’s findings, some of the researcher suggest using a high temperature profile could increase the viscosity and modified the viscoelastic properties, but causing a reduction of mechanical properties. As for the differential scanning calorimetry analysis, it was found that the crystallization temperature and crystallization time decrease as a function of the number of extrusion cycles. Even though such drawbacks happened during recycling, there is a room to improve the properties of this recycled material. The improvement can be attained, by using the organophilic layered silicates and maleic anhydride grafted polypropylene compatibilizer. This step can improves significantly the mechanical properties of the recycled polypropylene (Tri Phuong *et al.*, 2008).

A method that could be considered to recycle polypropylene nanoclay is the reprocessing extrusion. Few researchers have tried to determine the influence of reprocessing or multiple extrusion steps on the properties of recycled polypropylene nanoclay. For an example, a research revealed that after four cycles, the thermal and mechanical properties of this material were decreasing as been expected. The more important fact is during recycling, the structure of this material was severely affected, which made the recycling process far more complex than traditional polymer (Touati *et al.*, 2011). However, the efforts of exploration the potential of this material to be recycled had been continued, even with limited number of cycles, lack of nanocomposites microscopic behavior analysis (Oikonomidou *et al.*, 2012), no comparison between the pristine, polypropylene/compatibilizer and complete polypropylene nanoclay, virgin PP and PP/compatibilizer mixtures, also short of findings in terms of mechanical and morphological characteristics (Silvano *et al.*, 2013). Then, the research continues with a study about polypropylene nanoclay, which was subjected to repeating 15 extrusion

cycles. Based on the results, the increment of processing cycles had reduced the resistance towards impact and Young's modulus. The properties decrease, due to poor filler-matrix interaction that was originated from the degradation of clay (Delva *et al.*, 2014).

Therefore, the most important notes about the reprocessing process is the degradation of thermal, thermal oxidation and thermal mechanical properties, due to aggressive shear and modification of the filler morphology. Hence, this process was influenced by several factors such as the composition and nature of raw materials, shear level, temperature, polluting agents and number of cycles (Dorigato and Pegoretti, 2013). These factors need to be taken care off, before proceeding the recycling process of polypropylene nanoclay nanocomposites.

Mechanical Properties of Recycled Polypropylene Nanoclay

The fundamental that comprise the reactions to any applied load is called the mechanical properties. The usefulness of a material and their range of service life can be predicted by these properties. Material identification and classification also can be determined. Typical properties that are commonly analyzed are strength, ductility, hardness, impact resistance, and fracture toughness. Mechanical properties are generally specific to product form such as sheet, plate, extrusion, casting, forging, and etc. Additionally, it is common to see mechanical property listed by the directional grain structure of the material (see "Relevant Websites section").

A research had been conducted specifically to study the effects of reprocessing cycle of polypropylene-nanoclay nanocomposites (PPNC) towards its mechanical properties. Research started from performing injection molding process towards PPNC. The flow of mechanical test was displayed in Fig. 1 (Othman *et al.*, 2017).

In this experiment, the average tensile strength value was obtained for 0%, 25%, 50%, 75%, and 100% recycled polypropylene nanoclay. The result of average tensile strength is illustrated in Table 1 (Othman *et al.*, 2017).

Table 1 showed that the sample of 0% PPNC, trial no. 4 produces the highest tensile strength with value 29.556 MPa. As for the sample of 25% PPNC, the highest value is trial no. 4 with value of 29.118 MPa. The highest value of 28.742 MPa at trial no. 4 was obtained from 50% PPNC, and the same trial number produced the highest value of 28.954 MPa for 75% of PPNC. Finally the highest value obtained for 100% PPNC was 28.831 MPa (Othman *et al.*, 2017).

For further research, samples of polypropylene nanoclay were produced and then measured using Shore hardness test and Charpy impact strength test method. Then, the product was crushed back into pellets for reprocessing cycles. The reprocessing process was repeated for four times. For comparative purpose, neat polypropylene (PP) also underwent the same reprocessing process as PPNC. Table 2 shows the results of hardness and impact strength obtained from the experiment (Othman *et al.*, 2016).

The highest hardness number obtained was 62 shore which was the result for the first reprocessing cycle of neat PP while the lowest hardness number obtained from the experiment was 57 shore which was the result for the fourth reprocessing cycle of PPNC. The highest impact strength result obtained was 0.40 J/m² which was the result for the first reprocessing cycle of neat PP

Fig. 1 The flow of mechanical test for recycled PPNC.

Table 1 Tensile strength value for 0%, 25%, 50%, 75% and 100% recycled polypropylene-nanoclay composites

Trial no.	MT (°C)	PP (%)	SS (%)	FT (s)	Tensile strength (MPa)				
					0% PPNC	25% PPNC	50% PPNC	75% PPNC	100% PPNC
1	160	60	50	1	29.457	28.858	27.730	28.615	28.320
2	160	70	60	2	29.328	29.096	27.620	28.193	28.246
3	160	80	70	3	28.842	28.791	28.045	28.828	27.763
4	165	60	50	3	29.556	29.118	28.742	28.954	28.187
5	165	70	60	1	28.808	28.621	28.558	28.367	28.107
6	165	80	70	2	29.315	28.438	28.454	28.420	27.765
7	170	60	50	2	29.386	27.456	28.611	28.831	26.726
8	170	70	60	3	26.384	28.694	28.485	28.696	28.217
9	170	80	70	1	27.604	28.449	28.090	27.960	28.036

Table 2 Average hardness number and impact strength of PPNC and PP after each cycle

Material	Hardness number (Shore)				Impact strength (J/m ²)			
	1st Cycle	2nd Cycle	3rd Cycle	4th Cycle	1st Cycle	2nd Cycle	3rd Cycle	4th Cycle
PP	62	61	61	59	0.40	0.32	0.29	0.28
PPNC	61	60	58	57	0.19	0.21	0.20	0.18

Note: Othman, M.H., Hasan, S., Ibrahim, M.H.I., Mat Sedik, N.A.N., 2016. Compounding of recycled clothes with polypropylene-nanoclay for injection molding feedstock, In: Proceedings of the Putrajaya International Built Environment, Technology and Engineering Conference (PIBEC2016), 24–25 September 2016. Hotel Bangi-Putrajaya, Bangi, Malaysia.

while the lowest impact strength result was 0.18 J/m² which was the result for fourth reprocessing cycle of PPNC. The findings of this research had been concluded that when the reprocessing cycle of PPNC increase, the hardness number and impact strength of PPNC decrease. The hardness number of PPNC decreased in a total of 6.56% from the first reprocessing cycle to fourth reprocessing cycle. Meanwhile, for impact strength of PPNC, the declination happened starting from second reprocessing cycle to fourth reprocessing cycle. The total declination was 14.29%. The impact strength of the first reprocessing was lower than the second reprocessing cycle by 10% due to some errors. It can be concluded, reprocessing cycle has affected the impact strength of PPNC more than it has affected the hardness of PPNC. However, when compared to neat PP, neat PP has higher hardness number and impact strength than PPNC (Othman *et al.*, 2016).

Conclusion and Future Trends

As for conclusion, this article had outline the important information related to the recycling of polypropylene nanoclay composites. The first part of this article is a brief introduction about polymer recycling. After that, an explanation was made about the effect of clay loading, preparation and the application of this material. The information was important because it will affect the recycling process and performance. Then, a review of mechanical properties for this material and its recycled compound have been elucidated.

In term of future trends, more studies were needed to gain more success in term of attaining good properties for recycled polypropylene, as well as improving the cost efficiency to make the process competitive. The good properties could be achieved, by focusing more towards the interaction and interfacial adhesion of polypropylene nanoclay. The use of compatibilizer, functionalizer and surface modifier could assist the process. More research was also needed to improve the filler through modification and combination of other material as well. Other advanced preparation method and optimization through statistical approach also the key points that should be considered for future development (Zare, 2013). More than that, efforts were also needed, in term of providing the correct tools for recycling such as using the sustainable material management, waste reduction model and reuse and recycling opportunities and demolition, so that the recycle process of polymer nanocomposite could be utilized more productively over their entire life cycles (see “Relevant Websites section”).

Recycling and Downstream Processing of Aluminium Alloys for Automotive Applications

Brij K Dhindaw, Gowrawaram SL Aditya, and Animesh Mandal, Indian Institute of Technology Bhubaneswar, Argul, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

Energy Consideration and Sustainability of Aluminium Alloys

The aluminium industry is making continuous improvements in the environmental efficiency of producing aluminium through primary and secondary processes. According to Miller *et al.* (2000), A large difference in energy requirements for production of primary aluminium (113 GJ/t) vis-à-vis secondary aluminium (13.6 GJ/t) has prompted recycling of aluminium alloys. The benefit of recycling to the aluminium industry has recently been addressed numerically by Choate and Green in which they showed that production of primary aluminium requires ~45 kWh of energy and emits ~12 kg of CO₂ for each kilogram, whereas the studies of Miller *et al.* (2000) show that secondary aluminium produced from scrap requires only ~2.8 kWh of energy and emits ~0.6 kg of CO₂ for each kilogram of aluminium recovered. A 10% increase in aluminium end of life recycling rates decreases industry greenhouse gas emissions by 15%. Primary aluminium melt contains a higher level of sodium, aluminium carbide and non-metallic inclusions; whereas Das (2006) says recycled aluminium tends to have increased levels of hydrogen, calcium and large oxide inclusions due to high temperatures used for melting secondary aluminium. The use of aluminium to make industrial products inherently brings sustainable results. As an example, structures built with aluminium exteriors naturally reflect light and remain cooler.

Existing Technologies for Recycling of Aluminium Alloy Scraps

In the current recycling infrastructure, mixed aluminium scrap composed of castings and wrought pieces are sold by automotive shredders to the secondary aluminium industry for recycling into foundry alloys as per Das (2006). Recycled aluminium may involve a mixture of alloys from a fairly wide variety of sources, including a selection of castings containing rather high percentages of Si. While most of this metal may be used in new castings, there is a significant challenge in its use as sheet, plate, forgings, and extrusions.

It is estimated that, by 2020, worldwide consumption of aluminium products is expected to double, driven by growth and industrialization in China, India, Russia, and Brazil. Modern automotive recyclers use a number of efficient processes to recover valuable materials from end-of-life vehicles. Mechanical or physical recycling of vehicles includes magnetic separation, eddy current separation and density-based separation. Some of the new technologies in aluminium scrap processing includes colour sorting and Laser induced breakdown spectroscopy (LIBS). Apart from conventional re-melting process to recycle aluminium alloys, solid state recycling process utilizing compression and extrusion at room or moderate temperature has been developed for significant energy savings. Solid state recycling is limited to turning and chips and is a challenge for automotive aluminium scrap due to inhomogeneous property of the scrap, iron contamination and organic coating. In one of the work, Das (2006) have emphasised on developing and evaluating recycle-friendly aluminium alloys. Such an approach requires compositions with (a) relatively broad specification limits on major alloying elements such as Cu and Mg and (b) more tolerant (i.e., higher) limits on Fe, Si, and other impurities, without significant restriction on performance characteristics for many applications.

Recycling of Automotive Aluminium Alloy Scraps

Aluminium Alloys Used in Automotive Sectors

The automotive sector has provided the maximum impetus for recycling of aluminium alloys being one of the highest consumers. Most of the reclaimed aluminium today goes back into low value automotive castings, which comprises ~75% of the aluminium in cars rather than higher-value wrought products. It was reported that each year more than 50 million vehicles reach the end of their life worldwide. As per Miller *et al.* (2000) the average total aluminium content per car for European cars was 140 kg in 2012 which can be divided as follows – Power-train (69 kg), Chassis and suspension (37 kg) and car body (26 kg).

Typical aluminium alloys used in automobiles include, (a) cast alloys - A359, A356, A361, A413, A332 – which account for 78% and (b) wrought alloys – AA6060, AA6082, A3003, AA5182, AA5754, AA6016, AA7020 – which account for 22%. Apart from conventional alloys, new and lighter aluminium alloys for automotive applications are being developed to meet the need for super light cars that cannot be met by the present aluminium alloys. Few examples being, high Mg containing 5xxx alloy for warm forming and new 6xxx alloys for structural applications and fast paint bake response to withstand thermally

induced plastic deformation. All of the aluminium alloys above need to follow four basic design criteria to be considered for automobile applications: maximum property-to-weight ratio, minimum number of alloys in any one part, choosing standard alloy families based on IADS standard and avoiding expensive/exotic alloying elements. The difficulty in recycling wrought aluminium alloys is its low tolerance, the ability of an alloy to absorb impurities, which is not normally present in its composition.

Alloy Design and Application Challenge in Recycling of Automotive Aluminium Alloy Scraps

Currently the automotive industry uses 5000 series formable alloys for the outer panel applications and the heat treatable 6000 series alloys for the inner panel applications. The current challenge is to make an alloy that can be used for both the inner and outer panel applications. Such an alloy will result in improved recycling efficiency. Hoogovens rolled products Duffel, has developed 6xxx alloy within the EN6016 specification (HANV6016) for outer panels and a highly formable 5xxx alloy, (HANV5182) registered as inner-lite, for inner panels within the EN5182 specification. The mechanical properties of these alloys were comparable to that of the traditional alloys. Attempts are being made to design a common alloy for the entire automobile.

Current Projected Trends in Recycling of Aluminium Alloys

The usual method of recycling is re-melting of the scrap and subsequent processing it in numerous ways. One of the recently developed techniques is the hot press technique which is a melt less recycling technique. A6061 aluminium chips were recycled using by this technique under various operating temperatures and holding times. Yusuf *et al.* (2017), showed that the mechanical properties of the recycled samples showed similar properties to that of A6061 T4 tempered sheets.

One of the issues with recycling by re-melting route is the build-up of oxides. The oxides formed during the service of a material get agglomerated during the re-melting and unless these are removed or broken and uniformly distributed in the melt, recycling will not be effective. This problem is addressed using the melt conditioning treatment. This not only solves the problem of oxide build up but also eliminates the need for the addition of grain refiners. Melt treatment before casting is called melt conditioning. The currently used melt conditioning techniques utilize the principle of shear to disperse the particles. Techniques have been developed to shear the melt at different speed and accordingly are classified into high shear and low shear melt conditioning techniques. The high shear melt conditioning process is done using two techniques – (a) twin screw mechanism which uses high speed rotating twin blades to shear the melt and, (b) rotor stator mechanism which uses a rotor to do the same. Both are limited to batch processing of melts. But for a continuous process involving larger quantities of melt, low shear processes would be much suitable. One such process is the slope casting technique. This equipment can be subjected to vibrations to increase the effective of particle dispersion using the low shear process.

Fundamentals of Recycling Automotive Aluminium Alloy Scraps

Automotive aluminium alloy scraps contain particles of various size, nature and morphology. A fraction of the particles with favourable lattice registry will act as potent nucleation sites.

The traditional heterogeneous nucleation theory considers the balance between the interfacial energy changes during the creation of the spherical cap on the substrate and uses contact angle as a measure of the substrate potency. The energy barrier for the nucleation is determined by the energy fluctuation in the melt and a steady state nucleation rate can be derived as a function of temperature by statistical analysis. However this classical theory will be invalid for the potent nucleating substrates where the contact angle is so small (effectively zero) that the creation of a spherical cap becomes unphysical. Heterogeneous nucleation involving potent substrates is better treated as an thermal and deterministic process where the number of nuclei depends on the driving force only and is independent of time. This lead to the development of the free growth model for grain initiation on a potent surface. As per the free growth model by Fan (2013) suggests that a new phase could start to grow freely without any delay due to the very small dimensions of the substrate which facilitates fast under cooling.

At the atomic level, the process of heterogeneous nucleation on a potent substrate can be considered to be atom-by-atom building of the initial solid phase on a template. Therefore, the lattice matching across the solid/substrate interface should play an important role in this process. Relevant to this process is epitaxial growth of a thin layer of one material on the surface of another material (substrate). Scientific basis for the epitaxial growth of strained layers on a substrate originates from the theory of Frank and Vander Merve. Fan (2013) theory predicts that a coherent layer of a crystal can grow on a substrate with a slight lattice misfit provided the thickness of the layer is less than a crystal thickness (h_c) (Figs. 1 and 2).

In the schematic (a) sketch shows the L/N interface before the growth of the PS layer ($h = 0$); (b) sketch shows the initial formation of the pseudomorphic solid (PS) with a coherent PS/N interface; and (c) sketch shows the completion of the epitaxial nucleation at a critical thickness (h_c) by creation of misfit dislocations at the S/N interface to change the PS layer into the solid and to convert the coherent PS/N interface to a semicoherent S/N interface.

The lattice misfit of aluminium with commonly found oxides like MgO, Al_2O_3 and $MgAl_2O_4$ in the recycled scrap is 3.2%, 8.36% and 12.93% which is comparable with the traditionally used grain refiner TiB_2 which has a lattice misfit of 4.22%. Hence the

Fig. 1 Schematic of the epitaxial model for heterogeneous nucleation.

Fig. 2 Schematic illustration of an inclined slope vibrating setup.

oxides can act as the potent nucleants for grain refining. The grain refining increases the number of grains per unit area which in turn increases the number of grain boundaries to obstruct the motion of the dislocations. The pile up of the dislocations causes an increase the strength of the material. This entire phenomenon is explained by the Hall Petch relation which gives the effect of grain size on the yield stress (σ_y) of the material.

$$\sigma_y = \sigma_i + kd^{-1/2}$$

Where σ_i is the yield stress of the material when there are no grain boundaries present in the material. K is a constant and d is the average grain diameter. Hence the yield strength increases with decreasing grain diameter.

Microstructure-Property Relationship in Aluminium Alloys Produced by Slope Casting

The evolution of microstructure in aluminium alloys produced using slope casting is discussed. The patented (Patent application no.:201831030977) low shear vibration melt conditioning setup was developed in the authors' laboratory that includes a stainless-steel vibrating slope. This setup is suitable for batch wise casting and continuous casting system as well.

The effectiveness of slope casting was demonstrated using two cast alloys, A356 and Al-7Si in one of the work by Jha *et al.* (2018), which is summarized in this section. The macrostructure of vertical cross-section of A356 alloy cast under three different conditions, i.e., as cast condition, cast after flowing through the slope and cast after flowing through the slope subjected to vibration is shown in Fig. 3. The macrostructure consists of columnar grains at the periphery and equiaxed grains at the casting interior (Fig. 3(a)). When the alloy was passed along the slope, fine equiaxed grains are observed throughout the macrostructure (Fig. 3(b)) as compared to Fig. 3(a). However, in Fig. 3(b) the grain size at the casting interior is fine and relatively coarser at the edges. In the case where the alloy is cast after flowing through the slope subjected to vibration, the presence of fine grains are seen uniformly throughout the macrostructure (Fig. 3(c)). The grain size as per Jha *et al.* (2018) in this case was found to be finer (118 μm) as compared to the alloy cast without any vibration (155 μm).

Subjecting the melt to low shear during the flow through the slope helps in fragmentation of oxide films (Al_2O_3 , MgO and AlMg_2O_4) and consequently increasing the number of nuclei. The problem with agglomerated particles is that when one oxide particle would nucleate α -Al, due to local recalescence other oxide particles would not be able to nucleate α -Al grains. Thus, shearing increases number of individual oxide particles by breaking the oxide films. A combined action of shearing and vibrations come into play to form a homogeneous refined microstructure. Similar melt conditioning experiments were carried out for Al-7 wt% Si alloy and the microstructures (Fig. 4). The eutectic silicon is partially refined when the melt is cast along the slope subjected to vibration, and the grain

Fig. 3 Macrostructure of A356 alloy cast under different conditions (a) as cast condition, (b) cast after flowing through the slope and (c) cast after flowing through the slope subjected to vibration. Reproduced from Jha, S., Aditya, G.S.L., Mandal, A., Dhindaw, B.K., 2018. Microstructural changes in hypoeutectic Al-Si alloys by low shear and vibration induced melt conditioning setup. Transactions of the Indian Institute of Metals 71 (11), 2783–2787.

Fig. 4 Microstructure of Al-7Si alloy cast under different conditions (a) as cast condition, (b) cast after flowing through the slope and (c) cast after flowing through the slope subjected to vibration. Transactions of the Indian Institute of Metals 71 (11), 2783–2787.

Table 1 Grain size of alloys (in microns) cast under different conditions

	<i>As cast condition</i>	<i>Without vibration of slope</i>	<i>With vibration of slope</i>
Al-7Si alloy	210 ± 10	145 ± 14	122 ± 27
A356 alloy	184 ± 49	155 ± 23	118 ± 19

size of the alloy subjected to vibration ($122 \pm 27 \mu\text{m}$) showing refinement compared to that of without vibration ($145 \pm 14 \mu\text{m}$). The summary of grain size of both alloys under different conditions is given in [Table 1](#).

It must be mentioned that the effect of vibrating the slope is prominent in A356 alloy possibly due to the presence of additional Mg which form bi-oxides and promote heterogeneous nucleation.

Thus, melt conditioning can be obtained by applying high shearing action and low shearing action in aluminium alloys to effectively obtain a refined microstructure. The presence of oxide forming elements like Mg helps the cause by acting as effective nucleating sites. It can be concluded that low shear melt conditioning with vibrations can be used as an effective technique to refine the recycled aluminium alloys which inherently have oxides present in them.

Downstream Processing of Aluminium Alloys

Direct Chill (DC) Casting and Other Sustainable Processes

Production of aluminium sheets by continuous casting route offers an opportunity to substantially reduce the cost as compared to conventional DC casting and hot mill method.

DC casting is a vertical semi-continuous casting process used for fabrication of cylindrical billets or rectangular ingots/blooms for Al, Cu and Mg alloys. The mould used in DC casting process is usually very short (75–150 mm). The casting rate is normally 50–150 mm/min. In the process the molten melt is poured onto a starter block which immediately solidifies the melt due to the difference in temperatures (direct chill). This starter block is moved downward to increase the mushy zone (semi solid zone) which will facilitate the formation of the final product, usually a billet. The mould walls are cooled continuously with a water film. Most of heat (~80%) is extracted by the direct chill and only 20% is removed by heat transfer through the mould wall. The main benefit of DC casting is that the solidification (and the formation of structure and defects) occurs in relatively narrow layer of a billet and can be well controlled.

Hot milling is another predominant downstream process where the metal is rolled between rolls above the recrystallization temperature of the metal. The number of rolls used depends on dimensions of the final product. The surface defects are eliminated to a maximum extent but rolling defects like alligatoring, buckling and others are commonly seen in the final products due to the differences of the speed of the rolls, roll loads and geometry of the rolls.

Twin-roll casting (TRC) process, a technique for producing aluminium sheets directly from liquid metal, has gained popularity due to lower greenhouse emissions, low capital investment and possibilities of easy diversification. [Barekar et al. \(2014a\)](#) tells that it consists of a pair of robust rolls capable of withstanding the high roll torques and roll separation forces. Based on the method in which the molten melt is allowed to pass through the rolls, the TRC processes are classified into two types: (i) horizontal twin roll caster [Fig. 5\(a\)](#) (ii) vertical twin roll caster [Fig. 5\(b\)](#).

The various regions which determine the quality of the strip after the completion of TRC process are indicated in [Fig. 6](#) as described by [Barekar and Dhindaw, \(2014b\)](#). These regions are prominently controlled by roll speed, pouring temperature or superheat of the melt, thickness of the sheet and alloy composition.

Few studies carried out on TRC and slope casting of aluminium alloys by our group are highlighted in the subsequent section. [Barekar et al. \(2014a\)](#) work, TRC and melt conditioned TRC (MCTRC) sheets of Al-5 wt% Mg alloy were produced using laboratory scale horizontal twin roll casting process. Al-5 wt% alloy was chosen as there is projected demand to accommodate long freezing range alloys for TRC. Another arrangement involved melt conditioning of Al-5 wt% Mg alloy, wherein rotor-stator type of high shear device rotating at 5000 rpm was employed to disperse naturally occurring oxides in the melt causing grain refinement. The sheets so obtained are referred to as MCTRC sheets. Both TRC and MCTRC sheets were deformed by cold rolling (10% reduction) and homogenized at 550°C for 1 h. The sheets were further cold rolled to a final thickness of $1.7 \pm 0.1 \text{ mm}$ (66% reduction) followed by homogenization at 300°C for 1 h.

[Fig. 7](#) shows that as cast TRC sheets have non-uniform microstructure with coarse α -Al grains of average size of $380 \pm 17 \mu\text{m}$, while MCTRC sheets have relatively fine equiaxed grains of average size of $245 \pm 87 \mu\text{m}$. Channel segregates comprising of low melting point regions are seen at the centre of sheets. They appear as thick black features in TRC strip ([Fig. 7\(a\)](#)) and much finer and uniformly distributed in MCTRC sheet ([Fig. 7\(b\)](#)).

The microstructure across the thickness in the transverse section of cold rolled and homogenized sheets prepared by TRC and MCTRC show α -Al grains of $96.5 \pm 9 \mu\text{m}$ and $69.2 \pm 6 \mu\text{m}$ respectively. [Fig. 8](#) below shows hardness contours across the transverse

Fig. 5 Schematic of (a) horizontal twin roll caster and (b) vertical twin roll caster.

Fig. 6 Schematic diagram of various regions from molten metal to formation of solidified sheet in a TRC process. Reproduced from Barekar, D., 2014b. Twin-roll casting of aluminum alloys – An overview. *Materials and Manufacturing Processes* 29 (6), 651–661.

section of cold rolled and homogenized TRC and MCTRC sheets. The hardness contours in MCTRC Al-5 wt% Mg sheet appears to be more uniform compared to TRC sheets. This suggests uniform distribution of Mg aided by faster homogenization in fine grained MCTRC sheets. The calculated values of time required for homogenization of as cast TRC and MCTRC samples of Al-5 wt% Mg alloys was found to be 9.5 and 3.9 h respectively.

The tensile plots for TRC and MCTRC cold rolled (66%) and homogenized at 300°C for 1 h is shown in Fig. 9. The higher tensile properties in MCTRC sheet as compared to TRC sheet is due to the following: (a) elimination of severe centre line segregation, (b) finer grain size and uniform microstructure.

Future Perspectives

Recycling is synonymous with reduction of energy as it consumes only a fraction of energy to produce a component with comparable properties with a primary alloy. The ever-increasing demand for aluminium alloy scraps by various countries is indicative of the importance of recycling and its downstream processing. This stems from the fact that lightweight aluminium is infinitely recyclable and is fast expanding. The recycled alloy components have a great potential to meet today's demanding

performance standards. To keep in pace with stringent demands of automotive sector, new technologies need to be developed which can be scaled up easily.

Acknowledgement

The authors would like to thank Dr. Nilam Barekar, BCAST, UK for conducting the tensile testing of the samples. Apart of the work was completed under the Uchchar Aviskar Yojana (Phase 1) program of MHRD. The authors would like to thank MHRD (Govt. of India) and NALCO, India for funding part of the research presented.

Renewable and Sustainable Materials in Automotive Industry

Manojit Ghosh, Arkajit Ghosh, and Avinava Roy, Indian Institute of Engineering Science and Technology, Shibpur, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

Motivation for increased levels of renewability normally include: (a) having high electricity load responsible for considerable CO₂ emissions which, combined with rising market prices for electricity, results in significant economic and environmental burden (b) operating mostly in a carbon-intensive industry, as a result of which, emissions have higher than allowed carbon footprint levels. The automotive industry requires a huge bulk of raw materials, mostly metals. Depending on fresh resources at the initiation of every manufacturing process would impose a high demand on the available resources and cause their rapid depletion. It is thus, a natural consequence that renewable materials be used.

Renewable, recycled or innovative lightweight materials are not a new feature of automotive design. However, with an increased emphasis on the overall life cycle impact of a car, there has been a recent surge in research and development in this area of material science. A comprehensive account of such developments has been provided here, in order to identify and provide plausible solutions to the problem of increasing carbon footprint faced by the automotive industry presently.

Apart from measures taken to infuse renewability in the automobile industry, sustainability is another aspect that must be focussed on. The negative impacts of high carbon footprint, hazardous waste dumping, and poor landfill waste management have led to sustainable initiatives becoming more prevalent in many industries including the automotive industry. Environmentally-friendly and sustainable mobility is, therefore, a goal for most, if not all automakers, and not just an aspiration. However, it is clear that a perfect model of sustainable mobility cannot emerge from technology alone, but rather a lot of other relevant inputs. There have been multiple surveys looking into the current scenario of sustainability in the automotive industry. One of such reports, SMMT's 19th Sustainability Report, reviews data from 2017. It witnessed a healthy increase in the number of signatories and for the first time includes a materiality assessment, examining current, emerging and future priorities of vehicle manufacturers and suppliers, as well as other stakeholders, including government advisors, academics, charities, environmental NGOs and trade unions.

Present day car manufacturers have implemented methods like effective waste management, using more and more renewable energy sources and developing materials which improve the fuel efficiency of the vehicle.

The following parts suggest how the problems of increasing renewability and sustainability can be addressed in a systematic manner, thereby also enumerating the developments being made in terms of the materials selection, or the tailoring of materials to be used in the body of the car or the designs chosen. These measures would eventually go all the way in providing plausible solutions to the current problems.

Need for Renewable and Sustainable Materials

So far as the current scenario of automobile industry is concerned, it is going through a challenging situation considering so many aspects like its environmental, social, economic impact etc. If the basic problems are considered, they can be categorized into four major issues, which are (i) durability, (ii) huge and heavy material usage, (iii) higher fuel consumption and (iv) environmental pollution. To overcome the above-mentioned issues, concept of 'Sustainable and Renewable Development' is introduced. Some of the points are discussed below about how the sustainable and renewable approaches in automobile sector can resolve or restrict each of these problems.

Overcoming the Durability Challenge: Life Cycle Assessment (LCA)

Life cycle assessment is a process which is used to measure the environmental impacts due to a product from its constitution to end-of-life i.e., cradle-to-grave. According to Sundin (2004) the life of an industrial outcome can be classified into five parts, namely:-

(a) its extraction from raw materials, (b) manufacturing, (c) distribution, (d) use and finally (e) its end of life stage. According to Ashby (2009) while assessing the life cycle, environmental impact of the vehicle, energy consumption during its use stage is an indicator of its environmental burden. However, LCA measurement methods in association with the international standards ISO 14040, 14041, 14042, 14043 are important, especially at the inception and design stage. According to Pennington *et al.* (2004) and Govetto (2008) the ISO 14000 series can be classified into four different phases; which are: the goal and scope phase, the inventory analysis, the impact assessment, and interpretation phase. The first phase 'goal and scope' indicates the purpose, boundary, metrics and the input and output units that will be assessed and the second phase 'inventory analysis' mainly deals with the information collection on different aspects. The third phase was introduced to measure impact on environment due to first two phases. Finally, the last phase 'interpretation' is to talk about the conclusion and to give a brief model of first three phases.

Fig. 1 Physical product life cycle. Reproduced from Sundin, E., 2004. Product and Process Design for Successful Remanufacturing. Linköping: Linköping University Electronic Press.

Fig. 2 Vicious cycle of weight. Reproduced from Marathe, S.R., 2013. Light weighting in automotive industry, In: Proceedings of the Automotive Manufacturing Solutions India Conference 2013, ARAI, Pune.

The LCA of an automobile inspects the vehicle from primary i.e., raw material state to its end-of-life state. Refer to the diagram below (Fig. 1), which is basically a schematic diagram, better to say a flow chart representing the LCA of a vehicle.

By the life cycle assessment, we get to know about the suitable materials for the vehicles to be used in different purposes and for different time spans. The main criterion is to satisfy maximum durability. Thus, concept of sustainability comes into the picture. While assessing the end-of-life part, it is better if the materials of a car could be reused after a complete life cycle. Thus, the idea of recyclability and hence renewability is introduced.

Huge and Heavy Material Usage Related Problems: Introduction to Advanced Materials

Usage of heavy materials is currently a burden to the leading automobile producers due to its adverse effects on both environment and economy. Though the heavyweight materials provide significantly high strength, their high production cost and comparatively low cost-effectiveness compel producers to seek for advanced materials. These advanced materials are lightweight and have high strength as well. They can be high strength steels, aluminium, magnesium, reinforced plastics, metallic foams generated by various processing methods.

The need for light weighting can be well described by the cycle (Fig. 2):

The benefits of using lightweight materials can be categorized into economic and environmental benefits.

- *Economic advantages* – The first and foremost advantage of using lightweight materials is lower production and parts-assembling cost. When the overall body weight of a vehicle is reduced then smaller mechanical parts including engine, brakes, gear box are used and hence further weight reduction and cost minimization take place. The weight saving in the structural part can also be substituted by some luxury accessories or safety kits. Light weight vehicles also minimize the fuel consumption and are efficient for road handling.
- *Environmental advantages* – Vehicle weight directly impacts the fuel consumption therefore light-weighting lowers the CO₂ emission to a considerable extent. This is an example of direct weight saving. Indirect weight saving may also happen through downsizing of some components, lowering energy demand, shortening braking distance keeping the brake power same etc., 100 kg mass reduction achieved on a car saves 8 g of CO₂ per km at the exhaust pipe. (Reducing Mass Is Necessary to Reduce CO₂ Emissions, 2007).

Sustainable approaches are necessary to introduce lightweight high strength materials in place of conventional heavy materials and to get maximum benefits from the materials. On the other hand, renewable materials restrict the problem of huge material usage as these materials can again be used in other vehicles by recycling after end-of-life of a particular vehicle.

Restricting Higher Fuel Consumption: Mileage Enhancement

At its most fundamental, fuel-efficiency refers to the ability of a vehicle to extract energy from fuel. The more energy a vehicle can extract from fuel, the greater fuel-efficiency the vehicle is said to have. Similarly, the less energy a vehicle extracts, the less fuel-efficient the vehicle is. A vehicle is described as fuel-efficient if it is listed as having less than 6-L per 100 km (or greater than 16.5 km per litre). This standard prevents car manufacturers from listing their vehicles as “fuel-efficient” in cases when they quite palpably are not. It means that a vehicle needs 6-L of fuel, or less, to travel a distance of 100 km. It depends on the type of engine, too. In general, diesel engines are more fuel-efficient than petrol engines. They use compression ignition, which extracts more energy than spark plugs.

When it comes to improving fuel economy, engines, powertrains, fuels and batteries seem to get all the attention. To replace a car's traditional steel side panel or rooftop, usage of advanced lightweight materials at even the most basic car equipment can improve overall fuel efficiency. Reducing a vehicle's weight by 10% can improve fuel economy by 6%–8% (see “Relevant Websites section”). Steel is currently used as almost 60% of a vehicle's total weight. But in order to meet consumer demands and increasingly stringent federal fuel economy standards, automakers are looking to alternatives, including advanced high-strength steel, aluminium, magnesium and carbon fibre. Lightweight materials are a cost-effective way to boost fuel efficiency on conventional combustion engine vehicles and advanced automobiles like hybrids, electric vehicles and hydrogen fuel-cell vehicles.

Resolving Pollution Problems and Green Development

Only around 15%–20% of the energy in fuels is used to drive a car. The rest is rejected unused into the car's surroundings as waste heat or other losses. Thanks to advanced technologies, these losses are being reduced, step by step. Many already existing technologies, along with technologies that are not yet in mass production, are available to further improve the efficiency of cars.

The average CO₂ emissions level of new cars in the EU (as reported by car manufacturers) decreased from 170 grams per kilometre (g CO₂/km) in 2001–136 g/km in 2011 – a 20% reduction in 10 years (Fig. 3). As CO₂ emissions and fuel consumption are directly related to each other, this CO₂ emissions reduction can be expressed as a reduction in fuel consumption from roughly 7.0 litres per 100 kilometres (71/100 km) to 5.6 l/100 km.

The manufacturing of cars has been one aspect of the auto industry where green business practices have been lacking for years now. However, in the last five years, car manufacturing has made a significant transition into the green initiative by incorporating far more recyclable materials into car production, choosing fuel alternatives that allow companies to reduce their fossil fuel intakes, and making car parts that are overall more reliable and eco-friendlier (see “Relevant Websites section”).

When it comes to more recyclable materials that save fuel economy, Al comes into the picture because Al is much lightweight and malleable, this means that it can be used to manufacture any car, reduces the fuel intake of said cars, and also is easily recyclable likewise. Although cars cannot be completely comprised of aluminium for safety concerns, it is estimated that, by 2025, cars will be comprised of roughly 550 pounds of aluminium. This will ultimately lead to a far more efficient, cheaper, and more environmentally friendly mode of transportation that can be quickly recycled and redistributed likewise.

Fig. 3 Average CO₂ emission levels for new passenger cars in the EU. Reproduced from Anon, 2013. Reducing CO₂ and Fuel Consumption From New Cars: Assessing the Near-Term Technology Potential in the EU, ICCT. Available at: www.theicct.org/sites/default/files/publications/Briefing%20Technology%20Potential%20Long%20EN%20v3.pdf.

Methods to Incorporate Sustainability

Materials Selection

The automobile industry uses a tremendous number of materials to build various parts of the automobile (Hovorun *et al.*, 2017). For e.g., iron, aluminium, steel, glass, rubber, petroleum products, copper, steel and others. These materials have evolved greatly over the decades, becoming more sophisticated and safer. They have changed as new automotive manufacturing technologies have emerged over the years, and they are used in increasingly innovative ways. Based on both domestic and foreign sources of information, it follows that car manufacturers are constantly pushing to create the lightest cars possible to increase speed and power. Research and development into lightweight materials is essential for lowering their cost, increasing their recyclability, and maximising their fuel economy benefits. Light weighting without compromising on strength and speed properties is the present, and the future too, of the automotive manufacturing industry. It brings innovative materials to the frontline of design.

The categories into which the current raw materials, considering both interior and exterior, may be divided are: metals and their alloys (ferrous and non-ferrous), polymers, glass, textiles, coatings, fluids and lubricants etc.

From Fig. 4, one can conclude and in fact assume, for even a greater scenario (than the American industry), that steel and its various variants leads the percentage of materials usage, in the body of the car, while considering both interior and the exterior.

From here on, the ways to improvise upon the existing slew of materials shall be listed, so as to introduce the aspect of sustainability into the automotive industry, concentrating more on those materials which have relatively greater usage in the body of the car.

Fig. 5 represents a pictorial analysis of the various types of steel used for the different parts of the present car. In addition to that other variants have also been shown which can be used instead of steel in order to increase the strength to weight ratio of the car.

The following subparts separately highlight the various materials that can be used and up to what extent to guarantee a sustainable future of the automotive industry, keeping in mind these 3 criteria upon which selection (Jasinski *et al.*, 2016) has to be made: increased strength to weight ratio, durability, cost efficiency.

Fig. 4 Material distribution (in %) of an average American car by year. Reproduced from Henriksson, F., 2017. *Introducing New Materials in the Automotive Industry*. Linköping: Linköping University Electronic Press.

Fig. 5 Materials used most commonly for major vehicular structural components in the current fleet (www.cargroup.org/publication/).

Fig. 6 Parts made of metals, especially ferrous alloys (forums/forums/showthread.php?t=7278).

Steels

The automobile industry is imposing very high demands on steel because, first of all, it must meet two diametrically opposite criteria. On the one hand, the requirement to reduce the mass of products involves the use of high-strength materials, on the other – the growth requirements for the production of technology involve the use of high-plastic materials (see “Relevant Websites section”). **Fig. 6** indicates the different varieties of steels used in a typical car body.

The goal in making a car lighter is to increase performance and efficiency while maintaining safety and comfort. Roughly speaking, when a car’s weight is decreased by 10%, the efficiency of the vehicle can increase anywhere from 5% to 8%. This may not seem like a lot, but in the competitive automotive industry, it can make a world of difference (see “Relevant Websites section”).

Introducing increased strength to weight ratio:

An interesting variant in this aspect is the AHSS – Advanced High Strength Steel, whose microstructure has both ferritic and martensitic grains (Khedkar *et al.*, 2016). Such Dual Phase Steels (DPS) have the advantages like low yield strength, low yield to tensile strength ratio, roughly equal to 0.4–0.5, high initial strain hardening rates, good uniform elongation, good fatigue resistance, high Strength i.e., high energy absorbing capacity before failure.

New grades of AHSS enable carmakers to reduce vehicle weight by 25%–39% compared to conventional steel. When applied to a typical five-passenger family car, the overall weight of the vehicle is reduced by 170–270 kg, which corresponds to a lifetime saving of 3–4.5 tonnes of greenhouse gases over the vehicle’s total life cycle. This saving in emissions represents more than the total amount of CO₂ emitted during the production of all the steel in the vehicle (see “Relevant Websites section”).

There exist different varieties of AHSS based on their microstructural differences – TRIP (Transformation induced plasticity), DP (Dual Phase) – (refer **Fig. 7**), CP (Complex Phase), MS (Mild Steel).

Fig. 7 Microstructure of DPS.

Fig. 8 Ashby plot correlating elongation to tensile strengths of conventional steels and AHSSs (wenku.baidu.com/view/2e4419e4b9d528ea81c77975.html?re=view).

First generation

The 1990s saw the development of modern multiphase AHSS having tensile strength more than 450 MPa. Consequently, variants like DP, TRIP and CP steels having tensile strengths more than 1000 MPa were developed due to new processing lines, designed for integrated steel plants. Nowadays, by an adjustment of different constituents in their complex composite microstructure, a large range of mechanical properties can be offered by this steel family to the automotive industry. This excellent combination of mechanical properties and formability performance makes such steels the perfect choice for interior safety related panels (see "Relevant Websites section").

The stellar combination of strength and drawability as a result of the combination of strength and ductility, as well as the high strain hardenability gives DP Steels good strain redistribution capacity. For some applications it is important that the initial yield strength of steels is further increased by work hardening and the Bake Hardening (BH) process.

Steels having ferrite-martensite structure cover tensile strength ranging from 490 to 1180 MPa enabling them to be used in numerous car parts requiring resistance to denting, fatigue, intrusion, impact, and so on (Rana and Singh, 2017).

High tensile strength results in high fatigue properties. The high strength and strain hardening capacity of these steels combined with a strong BH effect give them excellent potential for reducing the weight of structural and closure parts. As shown, based on their high energy absorption capacity and fatigue strength, cold rolled dual-phase steels are particularly well suited for automotive structural and safety parts such as longitudinal beams, cross members and reinforcements. Fig. 8 depicts a comparative study by showing the Ashby plots of Elongation vs Tensile Strength for different types of High Strength Steels.

Second generation

For obtaining superior combinations of strength and ductility, so as to allow automobile parts, where integration of parts is possible, TWIP and Duplex/Triplex steels were developed, having Mn (12–35 wt%). Constituting of an fcc crystal structure, TWIP Steels have low Stacking Fault Energy (15–50 mJ/m²) at room temperature. Consequently, the plastic deformation is characterized by the pronounced dislocation glide and the dissociation of perfect dislocation to Shockley partial dislocations and formation of wide stacking faults.

With lowering stability of the austenite, the austenitic microstructure may transform to strain-induced ϵ -martensite and/or α' -martensite phase during plastic deformation, which is however undesirable. By twinning induced plasticity, these steels achieve outstanding combination of mechanical properties which makes them very attractive for automotive applications, especially where high strength and high ductility is required. Perfectly suited to manufacturing complex automotive parts e.g., side members the superior formability of these steels is ideally adapted to manufacturing components allowing only one or limited number of required forming operations. TWIP (Twinning-Induced Plasticity) steels boast of tensile strength ranging from 800 MPa to ~ 1200 MPa with a product tensile strength – total elongation up to $\sim 70,000$ MPa (Bracke *et al.*, 2009).

Triplex Steels, a low-density steel family, has considerably huge amounts of Carbon (up to 1.3%) and Mn (up to 30%). However, the added Mn should be less than 35% in order to avoid formation of brittle β -Mn. Aluminium was also introduced as an alloying element to increase the resistance to corrosion and oxidation. The utility of Triplex steels in the automotive industry has recently piqued interest owing to their strength-elongation compromise coupled with a low density. From the three phases that could be present in its microstructure – austenitic matrix, ferrite, and intra-granular χ -phases – the precipitation of the nanosized χ -phase inside austenite could lead to important precipitation hardening.

Third generation

These advanced high strength steels often have microstructures containing retained austenite, which undergo the TRIP and/or TWIP effect during straining or shear-band induced plasticity. Identified by a lean TRIP composition, such as TRIP bainitic ferrite (TBF) steels and Quench-and-Partitioning (Q&P) steels or medium Mn content lower than the above mentioned TWIP and Triplex steels – these steels are thereby called medium Mn TRIP steels.

Apart from medium Mn TRIP steels, all the other steel grades have the soft polygonal ferritic matrix generally replaced by a harder one consisting of either bainite (TBF steels) or tempered martensite (Q&P steels), respectively. The difference of hardness of the matrix and the inclusions is considerably lower using such a technique. More the homogeneous microstructure lowers the local micro-strains between matrix and inclusions, which, in turn, improves the bending and hole-expansion properties by a large margin. In addition to that, strained induced transformation of retained austenite to martensite during straining provides a much higher deep drawability. Consequently, these steels are suited for both bending and deep drawing operations rendering them especially suitable for manufacturing complex components like seat parts. The tensile strength of TBF and Q&P steels is > 1000 MPa with total elongations $> 10\%$ by superior bendability and hole expansion properties. Medium Mn TRIP steels are comprised of 4–7 wt% Mn having microstructures of ultrafine-grained ferritic matrix with a grain size typically less than $1 \mu\text{m}$ and a high-volume fraction of retained austenite usually up to 30 vol%. Tensile strength of these steels is usually > 1000 MPa along with total elongations in a range of 25%–40%.

Due to their higher ferrite potential compared to high Mn twinning-induced plasticity (TWIP) steels, medium Mn steels, exhibiting austenitic-ferritic microstructures, are hence suitable for third-generation advanced high-strength steel applications. Since the strain hardening characteristics of medium Mn steels are inferior to those of fully austenitic high Mn steels alloy design strategies to obtain fully austenitic medium Mn steels capable of the TWIP effect have been developed.

In order to achieve a fully austenitic microstructure, the martensite start temperature is lowered by raising the C concentration to > 1 mass%, thereby facilitating the formation of cementite. The cementite formed during cooling from austenitization temperature is counteracted by alloying with Al. The high affinity of Al for oxygen favors the formation of an oxide layer on the surface of steels. This oxide layer can in turn protect the bulk alloy from further oxidation and act as a barrier against the outward diffusion of C during high temperature solution annealing of high C steels. Furthermore, Al addition reduces the specific weight and can provide an additional tool to adjust the stability of austenite.

Fig. 9 illustrates the Ashby Plot for different generations of AHSSs correlating elongation to tensile strength.

Fig. 9 Ashby plot representing the correlating elongation to tensile strengths of the different generations of AHSSs.

Fig. 10 Aluminium's direct mass savings and market penetration. Reproduced from Anon, 2012. EAA Brochure "Aluminium in Cars". Ducker Report. Available at: www.scribd.com/document/157245456/EAA-Aluminium-in-Cars-Unlocking-the-Light-Weighting-Potential.

Aluminium (Al)

Aluminium is the material of interest to many automotive producers for making vehicle parts such as chassis, body due to its low density, good formability, and corrosion resistance (see "Relevant Websites section"). Aluminium alloys customized by appropriate variations in chemical composition and processing perfectly support many requirements, like the non-heat treatable Al-Mg alloys used in chassis optimized for superb resistance against intercrystalline corrosion and concurrent high strength or the heat treatable Al-Mg-Si alloys for extrusions and autobody sheet modified for improved age-hardening response during the automotive paint bake cycle (Hirsch, 2014).

The average total aluminium content per car for European cars was 140 kg in 2012. Its distribution has been analysed systematically as: (i) Power-train (engine, fuel system, liquid lines): 69 kg (25 components analysed) in engine block and cylinder head, transmission housings and radiators. (ii) Chassis and suspension (cradle, axle): 37 kg (17 components analysed) in wheels, suspension arms and steering systems. (iii) Car body (body-in-white (BIW), hoods, doors, wings, bumpers and interiors): 26 kg (20 components analysed) in bonnets and doors, front structure and bumper beams. Fig. 10 shows mass saving level due to use of aluminium in automobile and hence its market-penetration.

Aluminium is incorporated in vehicle body parts by three forms, like age-hardening Al-Mg-Si alloys (mainly 6xxx series alloys are used), preparing non heat-treatable Al-Mg-Mn alloys (5xxx alloys are important here), aluminium extrusions and casting.

By far, the biggest advantage offered by using aluminium in automobiles, including both engine and structural components, is the significant reduction in weight it provides. In fact, Al components weigh about half of equivalent steel components. This weight difference translates to much better fuel economy for drivers.

In addition, using Al doesn't require a compromise in the strength of vehicle components. It provides the same structural integrity as steel, so its weight-reducing advantages and increased fuel economy can really shine. The most important advantage of using Al over other materials in car industries is Al provides high strength-to-weight ratio, high corrosion resistance and advanced crash protection simultaneously.

In fact, Al components weigh about half of equivalent steel components. This weight difference translates in too much better fuel economy for drivers. In addition, using Al does not require a compromise in the strength of the vehicle components. It provides the same structural integrity as steel, so its weight-reducing advantages and increased fuel economy can really shine. Al and its alloys show very high corrosion resistance. So, from the durability perspective it is very beneficial to use Al in vehicle especially in the body parts. Al makes alloy with almost every metal to produce stronger and more qualified materials. Its 3xxx, 5xxx, 6xxx alloys are good examples of that. Al is much more efficient in crash protection than other metals currently in use. In the event of an accident, Al can absorb a lot more of the kinetic energy that would otherwise be transferred to human occupants of vehicles. Injury likelihoods are lessened as drivers and passengers are both kept safer. The scope of Aluminium usage in various car-parts is given in the Fig. 11.

Polymers

Plastics industry is very important in supporting the automotive industry. Automobile engineers are working together closely to optimize other systems, integrating injection and blow moulded parts offering a better product without expensive assembly work. Plastics are also finding their way into the structural design of the cars. There are four areas in automobile, interior, body and exterior, powertrain and chassis and light weighting which need highest-priority research and development with plastics (see "Relevant Websites section"). According to the European automobile researchers, it is possible to incorporate 350 kg engineering plastics to an average car. The Fig. 12 indicates the areas in which plastic can be useful in which form.

The following table shows the scope of use of some polymers in various parts of a car, their sources and key characteristics Table 1.

Fig. 11 Use of Al in various parts of a car. Reproduced from Mayyas, A., Qattawi, A., Omara, M., Shana, D., 2012. Design for sustainability in automotive industry: A comprehensive review. *Renewable and Sustainable Energy Reviews* 16, 1845–1862.

Fig. 12 Applicability of plastics in various car parts (www.deloitte.com/insights).

Other than advanced steels, Al alloys and polymers there are so many engineering materials which can enhance sustainability to automobile industry. A recently introduced technique is freeze casting of metals and ceramics to introduce lightweight foams. Titanium is very much responsive in this technique. NASA has already applied freeze casting technology to build advanced

Table 1 Polymers and their chief usage

Name of polymer	Source	Key advantages	Best applications
Polypropylene (PP)	Propylene monomer	It is rugged and unusually resistant to many chemical solvents, bases and acids.	Automotive bumpers, chemical tanks, cable insulation, gas cans, carpet fibers.
Polyurethane (PUR)	Organic units joined by carbamate links	Solid Polyurethane is an elastomeric material of exceptional physical properties including toughness, flexibility, and resistance to abrasion and temperature. Polyurethane has a broad hardness range, from eraser soft to bowling ball hard. Other polyurethane characteristics include extremely high flex-life, high load-bearing capacity and outstanding resistance to weather, ozone, radiation, oil, gasoline and most solvents.	Flexible foam seating, foam insulation panels, elastomeric wheels and tires, automotive suspension bushings, cushions, electrical potting compounds, hard plastic parts.
Poly-Vinyl-Chloride (PVC)	Vinyl-Chloride monomer	PVC has good flexibility, is flame retardant, and has good thermal stability, a high gloss, and low (to no) lead content. Polyvinyl chloride moulding compounds can be extruded, injection moulded, compression moulded, calendared, and blow moulded to form a huge variety of products, either rigid or flexible depending on the amount and type of plasticizers used.	Automobile instruments panels, sheathing of electrical cables, pipes, doors.
Acrylonitrile Butadiene Styrene (ABS)	ABS is a copolymer made by polymerizing styrene and acrylonitrile in the presence of polybutadiene.	The styrene gives the plastic a shiny, impervious surface. The butadiene, a rubbery substance, provides resilience even at low temperatures. A variety of modifications can be made to improve impact resistance, toughness, and heat resistance.	Automotive body parts, dashboards, wheel covers.

lightweight spacecraft materials. It will be of great pleasure to material scientists when freeze casted foams will be introduced to automobile sector.

Sustainable Designing

The present automobile industry is still primarily focused on using metals, instead of newer, more efficient materials. The need for product sustainability, however, is ultimately driving automobile design toward new materials technologies such as plastics and composites, which can be up to 10 times lighter than ferrous metals.

The motivation for going for a much lighter and streamlined design is driven by the observations from the following calculations:

$$\text{Drag force}(F_D) : F_D = \rho/2 \times v^2 \times c_d \times A \quad (1)$$

$$\text{Roll resistance}(F_R) : F_R = c_{ar} \times m \times g \times \cos\alpha \quad (2)$$

$$\text{Gradient resistance}(F_G) : F_G = m \times g \times \sin\alpha \quad (3)$$

$$\text{Acceleration resistance}(F_A) : F_A = m \times a \quad (4)$$

In Fig. 13, ρ = Air density, c_d = Drag coefficient, m = Mass of car, A = Cross-sectional area, c_r = Coefficient of rolling friction – CRF, g = Acceleration due to gravity, a = Acceleration of car, α = Angle of inclination.

Upon analysis of Eqs. (1)–(4), it can be observed that if ρ , c_d , c_r , g , a and α are treated as constants while considering the design of the car, then each of the resistances can be reduced by bringing down the mass (m) of the car. Moreover, the Drag Force can be reduced by decreasing the cross-sectional area (A). This forms the motivation for striving towards designs offering streamlined automobiles, thereby presenting lesser cross-sectional areas to air-drag.

Another aspect which comes into the scene, when considering the sustainability of the automotive industry is the economic viability of the overall car, ensuring that the quality of the car is not compromised in order to economize its material selection and manufacturing process (Mayyas et al., 2012).

Designing manufacturing processes based on the model of sustainability

In a search for flexibility, at the production level as well as in redefining the concept of cars, as friendly as possible, the automakers have been looking forward to extend its market that was restricted to only 20% of the planet by the end of the 20th century.

Fig. 13 Various forces acting on a moving car.

Fig. 14 Design based upon product life cycle. Reproduced from Peralta, M.E., Bárcena, M.M., González, F.A., 2017. On the sustainability of machining processes. Proposal for unified framework through the triple bottom line from an understanding review. *Journal of Cleaner Production* 142, 3890–3904.

Thereby, the primary step to assure this concept of “eco-car” or “green-car” is to reimagine and reengineer the way that cars are designed, incorporating environmental parameters from the very initial stages – manufacturing. LCA and eco-design have very important roles to play in this developing scenario as the methodological framework and a systematic and integrated approach towards the development of novel productive models, which can provide a sustainable basis for the automotive industry in the 21st century. Fig. 14 shows how product life cycle may affect design of an automobile.

In this sense, the future efforts on R&D at Renault, besides the short term ones such as the development of more efficient catalytic converters and particulate filters, are aiming for low or free emissions vehicles by using: (i) LPG (liquid petrol gas) (ii) Natural gas (iii) Electric vehicles (iv) Hybrid vehicles (combining electric and internal combustion engines) (v) Fuel Cells (hydrogen that emits nothing but water vapour) (Medina and Naveiro, 2003).

Apart from the design of the car itself, focus must also be shifted to the huge range of activities that the automotive industry spans, such as casting, machining, metal pressing, body assembly, surface treatment, painting and final assembly. Although these facilities do not represent a “high risk for the environment” (as set out in the 1996 European so-called Soveso directive), they nevertheless cause a series of environmental impacts that must be controlled.

These measures, which have already been adopted by leading car manufacturers around the world, include (i) reducing emissions per vehicle of Volatile Organic Compounds (VOCs), produced by paint solvents, (ii) using advanced technology

equipment (plasma torch) and developing control systems, to significantly reduce foundry dust emissions (iii) lowering of water consumption per car produced by a factor of 2.5 (iv) recovery of production waste.

Designing for recyclability

The rapid pace of automotive technology development has shown a significant growth in end-of-life vehicles (ELVs) waste streams globally. The number of ELVs is projected to increase continuously. ELV recycling plays an important role in maximising recovery of high-quality materials that can eventually be reused in a closed-loop vehicle manufacturing system. It is crucial to choose the proper combination of materials and joining techniques to achieve the optimal recycling. Most of the current recycling facilities are only capable of recovering metals cost-effectively, and the trend of new car designs is showing an increasing usage of light metals, plastics and composites that are not traditionally recovered. The flow diagram given under Fig. 15 shows the processes involved in recycling an automobile.

Design for recycling targets the same features as design for disassembly. It addresses more specifically the selection of materials and sets their recycling rate. It further points out the need to form recycled materials into new products. Particularly, fewer dissimilar materials in assemblies, or in subassemblies of products designed for disassembly, will improve the possibilities of material life extension. At present, there is a high recyclability rate for metallic vehicle components but a low recycling rate for the non-metallic materials.

The process of ELV recycling comprises of the following steps:

- Dismantling:** The recycling value of the components is highly increased in the dismantling process and allows the reusability of the product. The dismantling industry has a great potential. However, the full implementation of the EU directive for ELV dismantling is highly limited at present because it is labour intensive and uneconomical. Only a few high-value components are removed from the vehicle before sending to the shredding process. Dismantling companies can be branded into two types of businesses, the first comprises high-value parts businesses that remove and inventory the useful and high-value parts for resale. The other comprises scrap yard businesses that store the ELVs while the parts are gradually removed and then sold to local repair shops as well as Do It Yourself (DIY) owners.
- De-pollution processes:** De-pollution processes are seen as the removal of hazardous substances, battery, fluids, tires etc. It is good to note that high-value components are removed via manual disassembly. Several small facilities separate pure stream plastic for direct selling to recyclers and re-processors. The rest of the vehicle body is subjected to shredding operations for post-fragmentation recovery. Once the ferrous content has been recovered, the non-ferrous scraps are removed through dense media separation processes. The remaining components are sent to landfills.

Fig. 15 Recycling a vehicle. Reproduced from Klimisch, R.L., 1994. Designing the modern automobile for recycling. The Greening of Industrial Ecosystems. Washington, DC: National Academy Press, 165–170.

Fig. 16 Steps of recycling.

Fig. 17 Structure of a lead-acid battery, inside out.

- (c) Shredding process: This is another process of ELV disposal. Shredding industries can process large quantities of ELVs at capital-intensive sites. The main output from this process is ferrous metal, which is sent to steel industries for recycling. In the shredding process, rotating hammers rip parts of the compressed ELV, dropping it easily from the output grid where the light materials are separated from the heavy materials (such as plastic from steel). However, the process efficiency depends on the characteristics of the applied design. Therefore, recycling success can be increased by considering the hierarchies of the recycling process in the early design stages, which are listed out in [Fig. 16](#).

Recycling car batteries

Lithium-ion batteries ([Fig. 17](#)) are starting to be used in significant quantities for automotive propulsion. Because these batteries are expected to last the life of the vehicle, they will not be ending their useful lives in large numbers for about 10 years. They may subsequently be used for utility energy storage, but eventually their useful lives will end. The question is, what steps can be taken to ensure that these spent Li-ion batteries are recycled. In an ideal system, these batteries would be sent for responsible recycling and not be exported to developing countries with less stringent environmental, health, and safety regulations.

The lead-acid battery components are recycled by a simple process. First, the battery case is broken open, and the sulphuric acid electrolyte is drained out and collected. The plates and connectors can be removed from the case at this point and recovered whole. Alternatively, the drained battery can be sent to a hammer-mill for size reduction, and the plastic and lead can be separated by a simple sink-float device. The recovered lead (a low-melting metal) is re-melted and purified to make new battery components. Lead and sulphur emissions from secondary smelting is tightly regulated by the Environmental Protection Agency. The plastic is melted and moulded into new cases. The acid can be neutralized or processed to sulfate salts for various uses, such as the manufacture of soap. [Fig. 18](#) depicts the life cycle of a typical lead acid battery.

The recycling operation is profitable because recycled lead (taken back to its elemental form and purified) is known to be of high quality, so there is little incentive to export to places with less-stringent regulations. Some battery manufacturers prefer new

Fig. 18 Life-cycle of a battery (https://batteryuniversity.com/learn/article/how_to_restore_and_prolong_lead_acid_batteries).

Fig. 19 CLEVER – Compact low emission vehicle for urban transport (wired.com).

over the recycled lead. A key reason for the success of lead-acid battery recycling is that essentially all of the manufacturers use the same raw materials: lead, lead oxide, and sulphuric acid in a polypropylene case. As the battery design is similar for the manufacturers; automated technology can be used for battery disassembly. In summary, lead-acid recycling works well because it is profitable, it is illegal to dispose of the batteries without recycling, the battery disassembly is simple because of the standard design used, the battery chemistry does not require segregation, and the recycling process is simple.

Designing green cars – The cars of tomorrow

New designs have been suggested and are being developed even as you read this sentence. These designs would allow for greater fuel efficiency, reduced emissions per vehicle and high-cost efficiency among other benefits. A few of such designs have been listed below:

(1) CLEVER – (Fig. 19)

The CLEVER was originally conceived as a project at the Technical University of Berlin, as engineers aimed to design the lightest, cleanest city car possible. While still in prototyping stages under BMW, the final form of the CLEVER is expected to weigh less than 400 kg, and emit less than 60 g/km of carbon dioxide from its compressed natural gas engine. Perhaps the boldest design innovation by the team was giving the meter-wide vehicle the ability to lean like a motorcycle in corners, using kinetic energy in a far more efficient fashion. Power comes from a 230-cc single-cylinder engine that produces 12.4 kW (16.7 hp). BMW claims Clever can do zero to 60 km/h (37.2 mph) in around 7 s and tops out at approximately 100 km/h (62 mph). Clever is safer than it might look. It has special seat belts and a specially developed driver airbag that allowed Clever to comply with the Euro NCAP crash test requirements. The passengers, who sit tandem, are ensconced in a survival cell.

(2) SIMPLE – (Fig. 20)

“Sustainable and Innovative Mobility Product for Low Energy consumption” (SIMPLE) combines the best features of cars and motorbikes in one package, apparently, with the protected cabin of a car suited to the size and dynamics of a two-wheeler. The Simple does much of the work with hydraulics in place to prevent any accidents, stepping in during very slow traffic when the vehicle is the most unstable. Simple tips the scales at only 450 kg (920 pounds), so the internal combustion engine motivating it is commensurately small, putting out only 36 kW (48.2 hp). BMW says the three-wheeler will do zero to 62 mph in less than ten seconds and has a super-slippery drag coefficient of 0.18. The car’s most notable feature is it leans like a motorcycle in turns.

Fig. 20 SIMPLE by BMW (<https://www.evo.co.uk/bmw/10617/bmw-simple-concept/>).

Fig. 21 Antro SOLO (<https://hungarian-success-stories.com/2013/03/13/futuristic-hybrid-car-solo-duo-and-porto/>).

(3) Antro SOLO – A human-electric-hybrid (Fig. 21)

Antro's prototype has been built using a light magnesium alloy/carbon fibre frame and body construction and features electric assist for when the occupants tire or the driver is alone. Photovoltaic cells incorporated in the roof provide the power for the electric hub motors at each wheel and although the current model doesn't have one yet, the designers are aiming to install a fuel engine to give a longer range than the 12 miles or so that the electric motors currently provide. It is intended that the fuel engine will achieve fuel efficiency in the region of 150 miles to the gallon and reach speeds of around 87 mph.

Renewability in Automobile Industry – Vision of Developers

The term 'renewability' in automobile industry is the combination of two approaches that can be incorporated by the car developers- firstly, the use of recyclable materials and arrange for the ease of their recyclability and secondly, use of renewable energy sources in vehicles bypassing the huge usage of conventional energy sources. Renewability is the most important significant step towards green development, i.e., to deal with the pollution worries. The renewability measurements in automobile can be use of eco-friendly and bio-degradable products such as polymers, composites, advanced plastics in internal and external body parts, use of highly efficient batteries and thermoelectric materials etc. Various approaches to enhance renewability in automotive sector are discussed below.

Fig. 22 Local motors has 3D printed a fully working crowd-sourced car called the Strati (newatlas.com/local-motors-strati-imts/33846/).

Incorporating 3-D Printed Plastics and Thin Air Technology

Some automakers foresee the potential to use 3-D printing to create cars in widely distributed, smaller manufacturing facilities, using far fewer parts and some point to a future of rapid customization and personalization of cars: going from unique design, computer modeling, to building (printing) in days, not years. This new manufacturing model may also lead to further improvements in sustainability. While mainstream automakers already use 3-D printing for rapid prototyping to help bring cars to market faster, the race is on to build 3-D printed cars that meet both government safety standards and consumer performance expectations (Anon, 2017). Two major initiatives to introduce 3-D printing in automobile industry are: (i) The Divergent Manufacturing Platform enables manufacturers to quickly design and build new cars at a fraction of the cost and environmental effect of those produced in traditional factories. Using 3D printing as part of its unique NODE (see “Relevant Websites section”) system, Divergent 3D claims it can produce vehicle structures that are over 50% lighter with lower automotive production costs and fuel consumption. The NODE system is a new approach to manufacturing that incorporates 3D printed joints, which can connect carbon fibre structures to build an industrial strength chassis in just minutes. And (ii) Local motors designed first 3-D printed electric car “Strati”, which is made of carbon-fibre-reinforced plastic. The process of 3-D printing the Strati is quite efficient – it takes only a couple days to print the body of the vehicle, which is manufactured as one large piece (Fig. 22).

Another outstanding approach towards renewability by Ford is to produce car parts from thin air. They are aiming to make auto parts using plastics made in part from captured carbon dioxide waste streams. According to Ford researchers, they were inspired by plants that take in carbon dioxide and create complex sugars. In a similar manner, Ford is taking excess carbon dioxide and making durable plastics to use in vehicles. It will reduce the carbon-footprint of the producer as well.

These are the most advanced initiatives on waste management and undoubtedly these are having the power to incorporate recyclability in a sustainable manner.

Using Engineering Plastics (Polymers)

High performance polymers often known as engineering plastics can play an important role in vehicle production. Of course, they produce lightweight vehicles than metallic vehicles, which lead to increase fuel efficiency of the vehicle. But their advantages are not limited to lightweight production only, other chief advantages are like minimal corrosion, ease in recyclability, flexibility in integrating components, safety, comfort and economy etc. From the renewability point of view, first two advantages are mostly important. Corrosion minimization yields longer vehicle life and more importantly it lowers the amount of waste after end-of-life which allows most of the vehicle parts to undergo recycling. The recycling process of some polymers is much easier too than the metals which are used in automobile like Steel, Aluminium etc. The five most usable plastics in automotive industries are Polypropylene (PP), Polyurethane (PUR), Poly-vinyl-chloride (PVC) and Acrylonitrile Butadiene Styrene (ABS).

Plastics are in use in automobiles since the 1950s, but the latest innovations are really changing the industry for the better. Engineered plastics are on the way to replace aluminium and other metals in automobiles, with the average car interior now being made up of over 50% plastics (see “Relevant Websites Section”). Tough, lightweight plastics can help improve automotive fuel efficiency and when used plastics are recycled, it helps to keep valuable materials out of landfills so they can live another life as car parts or other products. Below some statistics are given for plastic usage by leading automobile producers (Anon, 2014):

Chrysler

Uses recycled polyurethane foam plastic in the seat cushions of its Jeep Grand Cherokee, and the wheel liners on the Jeep Wrangler and Chrysler 200 are made with 64% recycled plastics. In 2013, nearly 40% of the thermoplastics (the most widely used types of plastics in autos) in Chrysler’s European vehicles were recycled plastics.

Ford

Uses recycled plastics to create upholstery for passenger seat cushions in numerous models. For example, the seat fabric for each Focus is made with approximately 22 plastic water bottles. The company used more than 50 million pounds of post-consumer recycled plastics on the exterior of Ford vehicles made in North America – that equals nearly 18 pounds per vehicle on average. In the U.K., Ford also collects damaged bumpers to make plastic materials for replacement bumpers.

Honda

Recycles scrap bumpers generated during the manufacturing process. Plastics from bumpers produced at five Honda plants in the U.S. and Canada are reformulated and reused in Honda's supply chain to make mud and splash guards.

General motors

Uses air deflectors (used to direct air flow) for its Volt made from plastic caps, bottles, and other recycled materials. The company also uses plastic caps and shipping aids from its Fort Wayne facility to make radiator shrouds (used to protect the radiator) for the Chevrolet Silverado and GMC Sierra pickups built at that facility.

Renewable Energy Sources in Automotive Industry

The main aim of automobile producers these days is to restrict fuel using and reducing the usage of conventional energy sources, i.e., to control the carbon footprint of automotive industry considering the environmental issues. The major outcome of this concept is the recent bulk use of electric vehicles worldwide. Apparently, it seems that electric vehicles save conventional energy by not taking the fuel, but the real scenario is quite different.

Fig. 23 describes that electric cars need charging for their battery, charging stations need electricity to provide battery charging and finally these stations create additional pressure to thermal power stations and again conventional energy sources like coal, diesel is burnt. So, they are saving energy in a little amount which is not significant to restrict the hazardous impacts of automobile on environment.

It will be more fascinating if thermoelectric materials can be introduced in electric vehicle. In 2011 researchers introduced the idea of putting thermoelectric materials at exhaust pipes, which can generate significant amount of electricity and enhance the fuel efficiency of vehicle ([Matheson, 2014](#)). As there is no heat outcome in electric cars so, thermoelectric materials can be used in rooftop of the vehicle which will work only with solar energy and that transformed electricity can be used in small appliances like interior lights, music system, wipers, central locking system and in some tiny sensors. These materials should also be lightweight to be sustainable. Another energy saving technique that can save the battery, i.e., will aid the driver by increasing interval between two charging is regenerative braking system. The main function of this system is to store the lost kinetic energy due to braking and the stored energy can be utilised later. No doubt the use of thermoelectric materials and regenerative braking system will further enhance the energy efficiency of electric cars and maximum energy efficient vehicles can be obtained.

Fig. 23 Apparent energy saving vs real scenario for electric cars. Reproduced from Schneider, R., 2018. Materials Selection for a More Sustainable Automotive Future. Western Norway University of Applied Sciences.

Summary

This article briefly highlights the present challenges associated with a typical automobile industry and their possible solutions – which are incomplete without the concepts of renewability along with sustainability. It is discussed how sustainable approaches can be beneficial to achieve the most advanced state without creating an adverse impact as well as how renewability serves as the key for green development. Various methods and ongoing applications are given to incorporate renewability and sustainability. A comparative study between conventional and recently developed advanced materials has also been included. Finally, the article shows recent technologies, like electric cars, can be made more commercially efficient and environment friendly.

Renewable Biofuels and Their By-Products for Automotive Applications

Shailendra K Shukla, Indian Institute of Technology (BHU), Varanasi, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

The rate of economic development and urbanization has created a huge burden on the fossil fuel reserves of the world because they are the main source of primary energy. Due to the limited reserves of crude oil, the cost of petroleum based products is increasing continuously. In addition, these crude oil based products are also responsible for generation of greenhouse gasses which leads to catastrophic climate change. Automobile sector is the main consumer of petroleum based products, especially petrol and diesel, and hence also responsible for greenhouse gas emissions. Another reason is the fact that a large percentage of crude oil is imported from other countries oil fields. India meets over 82% of its crude requirement through imports and has been facing the onslaught of rising crude rates and Rupee depreciation which have been adding pressure on the Current Account Deficit (CAD), fiscal deficit and inflation. The use of conventional fuels leads to various problems such as environmental damage and health problems. The increasing industrialization and modernization of the world is leading to a sharp increase in demand for petroleum products. The current situation has sparked research interest in less polluting, non-petrochemical and renewable fuels for automobile application. Therefore, it is urgent to find fuel that can replace the conventional fuel. Reducing dependency on crude oil and minimizing the emissions from automotive sector is an important area in which researchers are working.

The development and use of alternate fuels, especially biofuels for automotive application, has attracted the researcher's attention. Biofuels offer several benefits, like reduced emissions, less dependency on conventional fuels and can be harvested on fallow lands which could provide jobs in rural areas, over conventional forms of fuels (Bluhm *et al.*, 2012; Dale *et al.*, 2010; Eriksson and Gustavsson, 2008; Ramos *et al.*, 2016). Biofuel can be produced from carbon rich sources such as plant biomass by fermentation and photosynthesis process. Since it can be produced from plant waste biomass, thus biofuels production is economical too. When bio-fuels are burnt, they emit low carbon and simultaneously control the production of poisonous substances, due to which air pollution levels are also low in the atmosphere. Technologically biofuel's properties suit all the existing automotive engine quality in most of the conditions. In addition, the engine running with biofuels needs less maintenance, low cost, no pollution and hence the long life of the vehicle as well as the environment.

Based on the types, biofuel can be found in all three forms, liquid, solid and gas such as wood charcoal, bioethanol, biobutanol, biodiesel, biohydrogen and biogas. First generation biofuels are produced directly from food crops to be used as biodiesel or bioethanol through fermentation. However, first generation biofuels have a number of associated problems. Most importantly, there is a contention of fuel versus food when it comes to these and in effect first generation biofuels have not found many takers across the world. This gave rise to the second and third generation biofuels. Second generation (2G) biofuels are produced from non-food crops such as wood, organic waste, food crop waste and specific biomass crops, therefore eliminating the main problem with first generation biofuels. Third generation biofuels (3G) on the other hand, mostly refers to those derived from algae. These biofuels come with their fair share of problems, including commercial, non-viability in some cases, the requirement for large areas of land/water as the case may be, contention on the actual carbon footprint across the entire value chain and many more.

Thus, as with most emerging opportunities, next generation biofuels present a promising future, but with challenges on the way. Hence, a balanced understanding of the opportunities the sector promises along with its inherent challenges is needed before investment decisions can be made. Now, in order to establish the biofuels as a potential alternate fuel for automotive applications the economic aspect must be studied by using life cycle cost analysis. Since, to proliferate in the market the final cost of the biofuels must be competitive with current petroleum products. The final cost of the biofuels is commonly assessed in terms of life cycle perspective (Singh *et al.*, 2010; Wang *et al.*, 2013), starting from the cultivation of the grains till the biofuel distribution in the market. The production of biofuels varies from place to place which affects its production cost. Therefore, life cycle cost of biofuels is an important aspect to determine the optimized cost and performance of the biofuel. In order to mitigate various consequences, alternative oilseeds are being investigated as biodiesel feedstocks.

Madhuca commonly known as the butter-nut tree is a large sized deciduous trees growing up to a height of 20 m is one of the promising tree species suitable for providing oil for biodiesel production, which conforms to international standards. It is commonly known as Mahua in Hindi. Madhuca is a widely adaptable tree, which can be grown on a wide variety of soils. For better growth and productivity, well drained deep loam or sandy loam soils are ideal but it also occurs on shallow stony, clayey and calcareous soils. A large variability exists in its fruits and oil percentage and there are no varieties available for block plantation. Mahua is indigenous to India; it is a frost resistant species that can grow in marginal areas of dry tropical and subtropical forests up. It can be found scattered in pastures, in crop fields in central India, and on river banks in semi-evergreen forests. It grows well where annual rainfall is between 500–1500 mm, and where temperatures are in the range of 2–46°C.

In this article the life cycle cost analysis of Mahua used for the production of biodiesel in India has been done. In the life cycle assessment, every stage like land purchasing, land preparation, nursery and plantation, irrigation, wedding, harvesting, drying and decertification, decortications, oil-extraction, filtering and finally trans-esterification is included.

Methodology

The tree has a potential of enhancing rural income. Being an evergreen variety and is a well adapted to varied weather condition. With its wide spreading branches and circular crown the tree presents a visually appealing structure. Seed yield ranges from 20 to 200 kg per tree every year, depending on its growth and development. The drying and decertification yield 70% kernel on the weight of seed. The kernel of seed contains about 50% oil.

For preparation of biodiesel, raw mahua (Seed) has been collected from the local area and filtered. The biodiesel from the vegetable oils has been prepared by the trans-esterification process. In this process, the vegetable oil has been heated to a temperature of about 60–65°C and methanol (30% of vegetable oil). Then, sodium hydroxide (NaOH) (1% of raw oil) has been added as a catalyst. Then, the mixture has been stirred for proper mixing and kept undisturbed for next 48 h. After completion of the reaction, the total mixture gets separated into two layers. The upper layer is methyl ester or biodiesel and the lower layer is glycerol. The upper layer (methyl ester) is separated and warm water of around 10% of the ester is added to remove any impurities like excess catalyst and methanol and suspended soap present in the ester and settled down for another 48 h. This process is called washing. Then the upper layer (around 85%) is decanted gently to another flask to rule out the presence of any impurity and the decanted oil is again heated to a temperature of around 60–65°C in order to evaporate the excess water. The biodiesel obtained are used for analysis purpose. **Fig. 1** shows step-by-step process of production of biodiesel from mahua.

Life Cycle Assessment and Discussion

In life cycle assessment the every stage like land purchasing, land preparation, nursery and plantation, irrigation, wedding, harvesting, drying and decertification, decortications, oil-extraction, filtering and finally trans-esterification should be included. Mahua trees are vegetatively propagated. Scions from the mother plant are grafted on year-old seedlings in July and are planted. Mahua responds positively to N, P, K fertilizers. Seeds are sown at a depth of 1.5–2.5 cm on raised beds. The seeds germinate in about ten days. One-month-old seedlings are transplanted in plastic containers of 15 × 25 cm. Six to twelve months old-seedlings are used for planting in the main field (5). The trees start bearing fruit in 10 years after planting and can yield fruits for up to 60 years. Older trees are more productive than young trees. Irrigation may be useful during fruit development, but should be avoided during flowering and leaf shedding. Man work 8 h/day (7). Before plantation, the field should be ready for plantation (Site preparation, alignment and stacking, digging of pits). The cost of FYM is 2.5 Rs./kg and the cost of fertilizer [Nitrogen(20 kg), Phosphate (10 kg), Potassium (15 kg)] are 108 Rs./ha, 90 Rs./ha, 960 Rs./ha (8). FYM, Fertilizer, irrigation, weeding and carriage charge are included up to 10 years. As per calculation ten yeas old Madhuca plantation has a sequestration capacity of 12 t/ha/year and 20 year old plantation has a sequestration capacity of about 27 t/ha/year.

Harvesting

In India, the fruits are harvested in May, June and July. Mahua trees are also harvested for their flowers and yield 100–150 kg of flower DM/tree/year. During 1st year seed yield 60 kg, 2nd year it will grow by 5% of its weight and 3rd year it will grow by 8% of its previous weight and 4th year up to 10th years it will grow by 10% by its previous weight. According to this, the labors also increase. Labor capacity of harvesting is 50 kg/day and for this they are paid 300 Rs./day. **Table 1** shows the amount of seeds/ha harvested for 10 years.

- Mahua seed.
- Mahua flower.

The growth rate of flower is 1% per year. Manpower increases accordingly. Open sun drying charge (900 Rs.) is also included every year in harvesting. The current price of the mahua flower is 20 Rs./kg. Hence total cost is found by quantity flowers and current price. In the first year this cost is Rs. 400,000.00/-. **Table 2** shows amount of profit from flowers/ha.

Total cost – Total investment = positive (profit). Here total cost is greater than total investment.

Decortication

Decortication is the process for separation of hull from seed yield. The decorticator is available in IIT (BHU), Varanasi of 1.5 kW with 150 kg/h capacity. **Table 3** shows the total cost in decortications. The extraction of oil from seed by screw press expeller of [5.5 kW with capacity 50 kg/h]10 kW with capacity 100 kg/h. Filtering of oil after oil extraction carried out with filter press of 1.5 kW with a capacity of 600 kg/h. oil and oil cake are available after crushing the seeds.

Fig. 1 Process of biodiesel production from Mahua.

Men work = amount (kg)/capacity of the decorticator (kg/h).

Man work hour = 8 h/day.

Hence, Men power cost = days × 561/-Rs. (9) [the minimum wage rate in rupee per month 16,858/-(skilled employees) hence 561/- per day].

Electricity consumed = capacity of decorticator (kW) × time period (h).

Commercial rate of electricity- 10 Rs./unit.

Transportation charge- according to amount.

Oil Extraction

After decortication, we get 70% seed by the weight of fruit. [Table 4](#) shows amount, time required and cost of oil extraction. Mahua oil is obtained from the kernel of the Mahua seed (*Madhuca Indica*) and contains 50%–55% oil.

Filtering

After filtering oil 2% impurities removed from the oil from the previous amount. [Table 5](#) shows the total cost of oil after filtration

Price of seed cake is 14 Rs./kg and glycerol is 50 Rs./liter.

Biodiesel per liter cost = total cost of biodiesel/total amount of biodiesel.

Table 8 Per liter cost of biodiesel

Amount of biodiesel (liter) 85% of oil	Reduction cost		Total cost of biodiesel (Rs.)	Cost per liter (Rs.)
	Seed cake cost (Rs.)	Glycerol cost (Rs.)		
2449	35,280	21,609.00	134,887.13	55.08
2571	37,044	22,689.45	138,318.14	53.79
2777	40,007.52	24,504.61	144,074.74	51.88
3055	44,008.27	26,955.07	151,763.65	49.68
3360	48,409.10	29,650.57	160,245.17	47.69
3696	53,250.01	32,615.63	169,602.12	45.88
4066	58,575.01	35,877.19	179,926.13	44.25
4473	64,432.51	39,464.91	191,318.61	42.77
4920	70,875.76	43,411.40	203,891.83	41.44
5412	77,963.34	47,752.54	217,770.08	40.24

Trans-Esterification

The main reaction for converting oil to biodiesel is called trans-esterification. The trans-esterification process reacts an alcohol (like methanol) with the triglyceride oils contained in vegetable oil, animal fats or recycled greases, forming fatty acid alkyl esters (biodiesel) and glycerin. The reaction requires heat and a strong base catalyst, such as sodium hydroxide or potassium hydroxide.

Table 6 shows the total cost of trans-esterification process.

Biodiesel plant capacity:

Feature: capacity – 50 kg/h onwards.

Fuel-electricity power required – 10 hp onwards.

Hence, 10 hp = 7460 W = 7.460 kW.

Pure oil amount is 2881.2–2881 liter, hence time taken by plant will be 57.62 h (near about 7 days).

Men power:- days × 561/- Rs.

Electricity:- capacity of plant (kW) × time period (h) = unit (kWh)

Commercial rate of electricity – 10 Rs./unit

First year:

7.460 kW × 57.62 h = 429.875 kWh – 10 × 429.875 kWh = 4298.75 Rs.

Chemicals used:-

Generally 30% methanol by volume of oil is used and liquid methanol price 28 Rs./liter from Bharat Biodiesel.

NaOH: –1% NaOH, generally by volume of oil. Price of NaOH is 39 Rs./kg.

Cost Analysis

The total cost of biodiesel production = [(land charge + cost of plantation + harvesting cost + decortication cost + oil extraction cost and filtering cost + trans-esterification cost) – cost of glycerol – cost of seed cake]

Till the 11th year Land charge and cost of plantation became fixed cost so it is separated into 10 years. The cost of seed cake and the cost of the glycerol are taken as reduction cost for increasing cost efficiency. **Tables 7** and **8** show total investment and per liter cost of biodiesel production respectively.

Conclusion

Life cycle cost benefit analysis presents following results:

- Total output is greater than total input and per liter biodiesel cost is decreases accordingly as production of biodiesel increases.
- Profit of mahua flower (279,100 Rs. 1st year) is greater than total cost of biodiesel (134,887.13 Rs. 1st year) hence *biodiesel is free of cost*.

There are another methods to increase the efficiency and reduce the cost. “Hielscher ultrasonic” devices are tested and proven in multiple plants to increase biodiesel yield and lower operational cost.

A Review of the Value-Added Chemicals and Materials From Bio-Based Lignin Feedstocks

Maryam Akbari, Adetoyese O Oyedun, and Amit Kumar, University of Alberta, Edmonton, AB, Canada

Introduction

The presence of a polymerized structure and polyelectrolyte properties are the foundation of all existing commercial applications of lignin except for combustion and synthetic vanillin production from lignin. Around 75% of commercial lignin is converted to dispersants, binders, emulsifiers, and sequestrants (Holladay *et al.*, 2007). These applications have low value and limited growth. Lignin's commercial application as polymeric and polyelectrolytic materials, however, can generate higher value products (Holladay *et al.*, 2007). The production of carbon fiber, adhesives, polymer modifiers, and resins benefits from the macromolecular structure of lignin. Lignin polymerization needs technological improvement with respect to catalyst development, fractionation, and purification (Strassberger *et al.*, 2014).

Carbon Fiber (CF)

Carbon fiber (CF) composites are lightweight but strong and substitute 40%–50% of the mass of steel in vehicles (Ragauskas *et al.*, 2014; Strassberger *et al.*, 2014). Currently, the commercial process for the production of carbon-fiber precursors that use polyacrylonitrile (PAN) is costly (Ragauskas *et al.*, 2014). Lignin is a low-cost source of carbon and is the ideal substitute for precursors and synthetic polymers such as PAN (Holladay *et al.*, 2007; Ragauskas *et al.*, 2014). Lignin-based carbon fiber, like other CF composites, is lightweight and strong and hence can considerably reduce vehicle weight and, accordingly, fuel use and economy (Holladay *et al.*, 2007; Strassberger *et al.*, 2014). However, inadequate understanding of the basic chemistry of carbon fiber production has retarded its progress (Ragauskas *et al.*, 2014). Carbon fiber production requires high purity lignin; all impurities must be removed (Strassberger *et al.*, 2014). Producing high-quality carbon fiber from lignin is challenging since purifying heterogenous complex lignin is not easy (Baker and Rials, 2013).

To produce lignin-based carbon fiber, lignin is first turned into fibers by extruding filaments from a melt (Ragauskas *et al.*, 2014). Electrospinning is the most straightforward and dominant approach for generating continuous micron and sub-micron diameter fibers from polymer solutions (Wang *et al.*, 2013; Dallmeyer *et al.*, 2010; García-Mateos *et al.*, 2017a). Lignin fibers are stabilized through oxidation and in the presence of air at 100–250°C to prevent fiber fusion during the following carbonization step (Holladay *et al.*, 2007; Ragauskas *et al.*, 2014; Ruiz-Rosas *et al.*, 2010). Stabilization can be done using oxygen in the presence of air or thermally using only heat.

The oxidized fibers then undergo carbonization at 600–1000°C or pyrolysis in an inert or nitrogen environment at 800–2400°C. Under these conditions, fibers are carbonized through the loss of CO₂, CO, H₂O, volatiles, and the oxidized components (Ragauskas *et al.*, 2014; Ruiz-Rosas *et al.*, 2010).

Lignin can be thermally pretreated before the extrusion of filaments. This pretreatment not only removes volatiles that disturb the integrity of fiber during thermal spinning but also reduces the hydroxyl content and hence decreases the intermolecular interactions (i.e., condenses lignin into macromolecules) and produces a well-structured microporous fiber (Kadla *et al.*, 2002; Ruiz-Rosas *et al.*, 2010). Thermal pretreatment under a vacuum results in a fusible lignin with excellent spinnability (Kadla *et al.*, 2002). Thermal fiber spinning and the stabilization that follows convert the thermoplastic nature of the lignins to thermosetting (Kadla *et al.*, 2002).

Norberg *et al.* (2013) were the first to thermally stabilize kraft lignin in the absence of oxygen. They found that softwoods stabilized quicker than hardwoods, and stabilization in the presence of air occurred in a shorter time. Stabilization and carbonization were completed in one step, only with different temperatures and times. These findings, if applied, can remarkably decrease the processing time and costs for the commercialization of CF production from lignin.

Ruiz-Rosas *et al.* (2010) produced CF through the one-step stabilization and carbonization method described above by Norberg *et al.* with and without platinum in the ethanol solution. Ethanol is a delignifying agent that dissolves lignin. The resulting CFs had a microporous structure, high oxidation resistance due to the defectless surface, and high structural order. However, the presence of Pt decreased the oxidation resistance of CF. Increasing the carbonization temperature produced CFs with a highly porous structure.

The incorporation of phosphorus in lignin carbon fibers loaded with Pt increased the fiber surface area and resulted in lower size and better distribution of Pt particles (García-Mateos *et al.*, 2017a). Phosphorus enhances fiber's resistance to oxidation and electro-oxidation. The produced carbon fibers can be used as electrodes without the need for a binder or conductivity promoter. The loaded Pt lignin fibers exhibited remarkable catalytic effects on methanol and ethanol electro-oxidation. The presence of phosphorus increased the higher heating rate by 10°C min^{−1} and reduced the isothermal stabilization step from 100 h to 1 h, thereby preventing the fibers from melting.

Acetic acid lignin (lignin from acetic acid pulping) from softwood can undergo faster heating rates than acetic acid lignin from hardwood (Uraki *et al.*, 2001). Moreover, ACFs from softwood acetic acid lignin exhibited higher specific surface areas than ACFs from hardwood acetic acid lignin. The former also offered greater adsorption capacity and satisfactory strength in the range of high-performance commercial ACFs.

Dallmeyer *et al.* (2010) investigated the electrospinning of seven different technical lignins and the effect of lignin structure on fiber formation. The results showed that only when poly(ethylene oxide) (1–5 wt%) was added could lignins be electrospun into continuous uniform fibers. The authors found a linear relation between fiber diameter and lignin concentration for all lignins. Electrospinning behavior and solution properties were greatly affected by lignin structure, intermolecular interactions, and viscosity.

Kubo and Kadla (2005) studied the effect of blending hardwood kraft lignin with synthetic polymer on the final fiber properties. Lignin was thermally blended with poly(ethylene terephthalate) (PET) and polypropylene (PP) and spun to obtain fibers, thermostabilized, and finally carbonized. PET-blend fibers could be stabilized at higher heating rates and had better thermal stability than corresponding homofibers. Carbon fiber yield decreased with decreasing proportions of lignin in the blend. Heterogeneous blend (PP-lignin) fibers exhibited a hollow and/or porous fiber, while homogeneous blend (PET-lignin) fibers displayed a smooth surface. The tensile and mechanical properties of blend fibers were comparable to those of commercially activated carbon fibers. The authors and their colleagues showed in another study that lignin polymer blends facilitated spinning, but the blends were thermally unstable and showed inter-fiber fusing during carbonization (Kadla *et al.*, 2002).

Tensile strength and modulus increased with decreasing fiber diameter, and the mechanical properties of carbon fibers from kraft lignin were found to be the same or better than non-commercially produced lignins. The overall carbon fiber yield was 40% for Alcell and 45% for kraft lignin (Kadla *et al.*, 2002). However, compared to petroleum-based carbon fibers, lignin-derived ones exhibited lower mechanical strength and were not graphitic structure-oriented. The latter is hard to reach in lignin-based carbon fibers (Ragauskas *et al.*, 2014). Also, there is not enough knowledge of the basic chemistry of the process or other sources of lignin used for the same application (Ragauskas *et al.*, 2014).

Kayocarbon fiber, the only commercial-scale carbon fiber lignin, was produced by Nippon Kayaku Co. in Japan, starting in 1967. The company folded in 1973. The lignin source was lignosulfonate, which was plasticized by poly(vinyl alcohol) (Johnson *et al.*, 1975).

Activated Carbon (AC)

Activated carbon (AC) is a highly porous carbonaceous material used to adsorb pollution from gaseous and aqueous solutions (Hayashi *et al.*, 2000). Lignin can be used as a precursor for the production of AC via chemical or physical activation to produce low-cost activated carbon.

In Hayashi *et al.*'s chemical activation study, lignin was mixed with an activating reagent (i.e., K_2CO_3 , Na_2CO_3 , KOH, NaOH, $ZnCl_2$, H_3PO_4) and water, kneaded, and then dried at 110°C. It was then carbonized at various temperatures in a nitrogen environment at the rate of 10°C min⁻¹ for 1 h. Finally, the sample was cooled, washed, and dried again (Hayashi *et al.*, 2000). Carbonization at 600°C in $ZnCl_2$ and H_3PO_4 activating reagents led to the highest surface areas for lignin-activated carbons, in the range of commercially activated carbons. The highest surface areas in the presence of alkali metal were obtained at 800°C and were much larger than commercially activated carbons except for Na_2CO_3 . $ZnCl_2$ limited tar formation and acted like a dehydration reagent; it encouraged char formation when the carbonization temperature was below 600°C. K_2CO_3 performed as a dehydrogenation reagent when the activation was below 500°C.

Fu *et al.* (2013) in their studies on physical activation, carbonized lignin in the absence of oxygen and at a heating rate of 15°C min⁻¹. They then activated the lignin using steam at a rate of 100 cm³ min⁻¹ and a pressure of 0.5 MPa. A carbonization temperature of 450°C for 60 min and an activation temperature of 725°C for 40 min resulted in the optimized activated carbon.

In one study, eucalyptus kraft lignin was partially gasified using CO_2 to produce AC (Rodríguez-Mirasol *et al.*, 1993). Temperature did not affect the porosity within the studied thermal range (750–900°C), but burn-off affected it substantially.

Proper use of AC as an adsorbent is defined based on its physical and chemical characteristics such as pore volumes, size, and surface areas (Cotoruelo *et al.*, 2012). Fu *et al.* (2013) found that lignin-activated carbon adsorbs methylene blue (MB) from wastewater better than other adsorbents made of industrial and agricultural wastes. Activated lignin-chitosan extruded (ALiCE) pellets exhibiting maximum adsorption capacity of 36.25 mg g⁻¹ also adsorbed MB and can absorb cationic organic pollutants from streams (Albadarin *et al.*, 2017).

AC adsorbent, prepared from the carbonization (350–800°C) of kraft lignin in N_2 atmosphere followed by CO_2 partial gasification (750–850°C) was able to remove p-nitrophenol (PNP) from an aqueous solution (Cotoruelo *et al.*, 2012).

Gonzalez-Serrano *et al.* (2004) produced ACs with a high surface area and well-structured micro- and mesoporosity from chemical activation via the pyrolysis of H_3PO_4 -impregnated kraft black liquor lignin. Best operating conditions were an impregnation ratio of 2 g H_3PO_4 per g lignin and an activation temperature of around 427°C, although other operating condition values also led to activated carbons with good adsorption capacities. The adsorption capacities of the produced activated carbons were comparable or even better than those of the other activated carbons for three main water toxic pollutants (phenol, Cr[VI] and 2,4,5-trichlorophenol).

Activated Carbon Fiber (ACF)

Unlike powder, fibers are flexible, and fibrous catalysts offer immobility, strong interaction of particles and support, short diffusion distance, and low resistance to flow through fiber bundles. As a novel porous material, activated carbon fiber (ACF) offers massive surface area and thus great adsorption capacity and many surface functional groups and with that strong reactivity and reduction properties, which is promising for catalyst preparation. ACFs were employed as support in Pt nanoparticle electrocatalysts (Pt/ACF) for direct alcohol fuel cells (alcohol oxidation) and exhibited double the anodic densities of alcohol oxidation as well as higher electrochemical stability and catalyst activity in alcohol oxidation than commercial Pt/C catalysts (Huang and Chen, 2008). Homogeneous Pt particles were uniformly dispersed on ACF. Fibers were carbonized at 850°C under N₂ flow before being activated using steam at the same temperature for 1 h to prepare Pt/ACF (Huang and Chen, 2008).

In a study by Shen *et al.* (2011) lignin-phenol-formaldehyde (LPF) was melt-spun and thermally treated to produce ACFs. When guaiacyl units in lignin were reacted with formaldehyde, lignin was found to be the dominant component affecting LPF thermal properties and AC pore size and related properties. Lignin's three-dimensional structure does not allow phenolic resin to be easily decomposed. It also inhibited the formation of large pores. 14% lignin incorporation into resin led to ACFs with great pore structure and adsorption characteristics.

Carbon Catalyst

Bedia *et al.* (2009) produced a carbon-based acid catalyst by a single-step chemical activation of H₃PO₄⁻ impregnated Alcell lignin under constant nitrogen flow (150 cm³ min⁻¹) and 2 h carbonization at a temperature of 500°C and a heating rate of 10°C min⁻¹. Incorporating acid surface groups by the chemical oxidation of the carbon surface was not required. Although there was a washing step, a large amount of phosphorus was left on the surface, which led the carbon surface to exhibit a particular chemistry with high amounts of surface acid groups that were thermally stable. The resulting catalyst converted 2-propanol to propylene via dehydration over the Brönsted acid sites that formed during the activation.

García-Mateos *et al.* (2017b) produced a basic activated carbon catalyst for the decomposition of alcohol that has various textural and surface properties resulting from the carbonization of kraft lignin. Kraft lignin has a high sodium compound content. Kraft lignin carbonization generated chars with a high oxygen group content on the surface of mainly carbonyl, quinone, and carbonate (sodium carbonate). These oxygen groups were the result of carbon oxidation and sulfur salt's reduction to sulfide. Washing and partially gasifying this char with CO₂ led to carbons with a basic surface of carbonyl and quinone groups and carbon basal planes that can act as electron donor sites. Carbonization occurred at temperatures of 500–900°C under a constant flow of nitrogen (150 cm³ min⁻¹). Using the basic activated carbon catalyst, 2-propanol, methanol, and ethanol transformed to acetone, formaldehyde, and acetaldehyde, respectively, at atmospheric pressures. Lignin catalyst conversions were not as great as expected but selectivities were higher than 80%.

Ruiz-Rosas *et al.* (2014) and Valero-Romero *et al.* (2014) studied lignin/zeolite mixture carbonization followed by inorganic template basic etching. Lignin-derived templated carbons exhibited an oxygen-rich surface as well as pyridine and pyridinic groups, which improved capacitance considerably compared to petroleum-based carbons. Hierarchical porous carbon can be used in carbon electrodes to produce electrochemical capacitors, in catalysis, energy storage, and adsorption, and can be prepared in a straightforward and environmentally friendly process using lignin as the carbon precursor and through the liquid phase impregnation method.

Fuel Cell

A fuel cell converts the chemical energy of a fuel directly into electricity without the need for prior processes such as gasification or structural changes. The direct carbon fuel cell (DCFC) has attracted increasing attention because of its superior efficiency (80% of the assumed value of a practical fuel cell) and low pollution (Lima *et al.*, 2013).

Lima *et al.* (2013) were the first to use a mixture of lignin or lignin and active carbon and electrolytes (50% mass ratio) as a fuel cell anode in which lignin was both fuel and electrode. Hydrophilicity and/or wettability are critical parameters for direct lignin fuel cell performance. Hence the pH of the lignins was changed by alkalinizing them to pH 10 by dissolving them in 0.1 M NaOH solution. Alkalified lignins exhibited higher maximum current density than the original lignins with 0.68–0.69 V open circuit voltage and 74–79 mA cm⁻² maximum current density. In addition, blending pure carbon with lignins (lignosulfonate ([LS], kraft [KL])) enhanced electrical conductivity because of carbon's high surface area, and KL + AC and LS + AC offered power densities of 12 and 24 mW cm⁻². Activated carbon has similar wettability to lignosulfonate and better than kraft lignin.

This application has not reached commercialization (Strassberger *et al.*, 2014), and because Lima *et al.*'s study was the first application of lignin in fuel cells, further study is required for adjustments and improvements of the DCFC using lignin. For example, the effect of lignin impurities should be tested on the key parameters (Lima *et al.*, 2013).

Electrode in Batteries

Increasing demand for energy storage has brought to the fore high-performance, inexpensive, renewable, and environmentally friendly materials like lignin (Kim *et al.*, 2014).

Rechargeable lithium-ion batteries are the most efficient storage devices and the most widely applied in portable electronic devices, emerging smart grids, and hybrid electric vehicles (Wang *et al.*, 2013). Because of their low cost, processability, and easy accessibility, carbonaceous materials have been found to be the most suitable for commercialization as electrodes in lithium-ion batteries. However, there are problems associated with the graphite, the current commercialized anode, such as poor energy density (Wang *et al.*, 2013). Also, new nanocarbon materials, though they benefit from remarkably better performance such as conductivity and accessible surface area, suffer from the high cost of the carbon precursors, nonrenewability, and the complex manufacturing processes, all of which are a barrier to commercial-scale production (Wang *et al.*, 2013; Milczarek and Inganäs, 2012). With respect to low-cost sodium-ion batteries, although they are promising for grid electricity storage, anode development is critical for their commercialization. Amorphous carbonaceous materials were found to be the most promising materials for this purpose. The problem with these carbonaceous materials is their high cost, a result of expensive precursors, and low carbon yield (Li *et al.*, 2016). Electrodes from renewable biopolymers offer low cost, better safety, and nontoxicity, and can be operated in water. The only problem associated with these electrodes may be self discharge (Milczarek and Inganäs, 2012). The high carbon content (> 60%) of lignin makes it the most attractive sustainable candidate as a precursor for carbonaceous materials (Nelson and Northey, 2004).

Popova *et al.* (2008) studied the feasibility of using graphite produced from hydrolysis lignin as an artificial graphite in electrodes. Graphite produced through the thermal modification of lignin exhibits high efficiency compared to other graphite materials, is a superior matrix for lithium intercalation, and can produce high specific energy content graphite electrodes.

Lignin nanocrystals confined on reduced graphene oxides have shown highly reversible and fast pseudocapacitive behavior (Kim *et al.*, 2014). Hybrid electrodes owe their outstanding capacitive characteristics to synergizing the fast and reversible redox charge transfer of quinone and the favorable interplay of hybrids. The resulting pseudocapacitors exhibited excellent cyclic performances of around 96% retention after 3000 cycles and a maximum capacitance of 432 F g⁻¹ (close to theoretical numbers), which was six times more than reduced graphene oxides.

Milczarek and Inganäs (2012) used lignin, an electronic insulator, as an additive in polypyrrole/lignin composite electrodes with low weight ratio (50 >) to prepare cathodes. Phenolic groups in lignin can be converted to quinones via oxidation processes. The quinone group in lignin can be used for proton and electron exchange and storage. The capacitance and charge density of the resulting composite were higher than most of the polypyrrole/carbon composites. Only polypyrrole/nanostructured carbons are reported to have values close to polypyrrole/lignin.

Li *et al.* (2016) also fabricated amorphous carbonaceous materials from a mixture of lignin and pitch. The emulsification interaction between pitch and lignin prevented the graphitization of pitch during carbonization and resulted in low-cost amorphous carbon material with a high carbon yield of 57%. AC was obtained by optimizing conditions that presented an appropriate morphology and microstructure along with a promising high reversible capacity of 254 mAh g⁻¹ and superb cycling stability and performance rate.

Supercapacitors

A supercapacitor is an energy storage device that is made of high-surface area carbon in aqueous electrolytes. Fuel cells show the highest specific energy, followed by batteries, but suffer from low specific power. Capacitors are exactly opposite; they have the highest specific power and the lowest specific energy. Supercapacitors have high specific power and medium specific energy systems and fill the gap between batteries and capacitors (Winter and Brodd, 2004). Lignin can be considered as a low-cost substitute for the production of porous carbons in large volumes. Different lignin types produce different porous carbons (Jeon *et al.*, 2015).

Jeon *et al.* (2015) were the first to carbonize lignin directly in a study in which a high surface area porous carbon was produced without any required activation steps or templating agents. Carbonization increased lignin porosity remarkably. This one-step process eliminated the chemical and physical activation steps and so reduced the complexity of the process and the production cost. Lower molecular weight lignins produce porous carbons with a higher surface area that are less defective than other carbons. The highest surface area (1092 m² g⁻¹) was found in porous carbon from kraft lignin. The carbonized lignin offered good capacity retention and high specific capacitance, energy density, and power.

Electrodes for supercapacitors can be obtained from the electrospinning of lignin/ethanol solutions followed by thermal conversion into interconnected and porous carbon fibers (CFs) with submicron diameters (Berenguer *et al.*, 2016). The CFs exhibited excellent storage performance including ultrafast charge-discharge and outstanding energy density and cyclability. Power and energy densities up to 61 kW kg⁻¹ and 10 Wh kg⁻¹, respectively, of the supercapacitor were in the range of or greater than top available structures. Also, it was found that more than 90% of the energy densities and 100% of the initial power of the supercapacitor was still available after 100,000 charge-discharge cycles at 5 A g⁻¹.

Hu *et al.* (2014) fabricated KOH-activated highly porous submicron-activated carbon fibers (ACFs) from low sulfonate alkali lignin into supercapacitors. Alkaline hydroxide activation caused hydrophobic CFs to be converted to hydrophilic ACFs with structures dissimilar to CFs. This different carbonaceous structure is the reason for the ACF supercapacitor's superb electrochemical properties. The KOH-activated ACF supercapacitor exhibited a notable 344 F g⁻¹ specific capacitance. Also, KOH-activated ACFs

generated a supercapacitor with superior electrochemical properties compared to the one prepared by NaOH-activated ACFs. However, both supercapacitors exhibited low equivalent series resistance and excellent cycling stability. After 5000 charge/discharge cycles, over 96% capacitance retention rates were reached. These outstanding performances proved lignin to have great potential for electrical energy storage.

Nanoparticles

Lignin nanoparticles (LNPs) have a wide range of applications, for example as coatings, composites, nanoglue drug delivery, Pickering emulsions, glue, microfluidic devices, antimicrobial materials, and wound healing (Lievonen *et al.*, 2016).

Lievonen *et al.* (2016) proposed a simple, straightforward technique to produce LNPs with an average diameter of 200–500 nm using tetrahydrofuran as the solvent. They conducted experiments in which the process occurred at room temperature in pure water and with no need for lignin chemical modification. Softwood kraft lignin was dissolved in tetrahydrofuran (THF), then water was added through dialysis. The dialysis bag solvent exchange offers great control over the concentration of nanoparticle dispersion. The process presented promising results for any kind of lignin soluble in THF. LNP dispersion was stable for more than two months in pure water and at atmospheric temperature; however, high salt concentration (>500 mM) or very low pH (<4) provoked accumulation. LNPs prepared using tetrahydrofuran had a uniform round shape and were more symmetric than the ones prepared using ethylene glycol. Pre-dialysis concentration of lignin affects the nanoparticle's final size. The surface charge of LNPs can be reversed, and when the polyelectrolytes that carry opposite charges (like poly[diallyldimethylammonium chloride]) were adsorbed, stable cationic LNPs were produced. THF could be recycled through evaporation and reused in the process. So this process requires a high amount of organic solvents and produces LNPs as an environmentally friendly dispersion.

Qian *et al.* (2014a) used alkali lignin from black liquor to make uniform nanometric colloidal spheres obtained through self-assembly. To form lignin colloidal spheres, lignin was acetylated followed by the gradual hydrophobic aggregation of acetylated lignin molecules while water was steadily added to the acetylated lignin-THF solutions. Acetylated lignin colloidal spheres are water-dispersive, while acetylated lignin itself is insoluble in water. Acetylated lignin colloids were found to have similar average density but a much larger average aggregated number than colloids from conventional polymers. The colloids from conventional polymers are prepared from block copolymers and their cores and shells are comprised of hydrophobic and hydrophilic blocks, respectively, but acetylated lignin colloids have cores and shells with stronger hydrophobicity and hydrophilicity abilities. Uniform colloidal spheres are prepared using this acetylation, followed by hydrophobic aggregation, although lignin-based aggregates are basically irregular. This method also provides a solution for lignin insolubility in water, which is one of the most important limitations for its industrial applications.

Through a simple, inexpensive, and novel method, Frangville *et al.* (2012) produced biodegradable, highly porous LNPs from lignin. They precipitated stable LNPs over wide ranges of pHs using diluted acid solutions from an ethylene glycol solution. Another method of producing LNPs is acidic precipitation of lignin from a basic solution. LNPs produced in their study by this method were found to be stable only at low pH. The resulting LNPs are non-toxic for microalgae and yeast and have great potential for substituting current non-biodegradable and possibly toxic nanoparticles.

Gonugunta *et al.* (2012) synthesized LNPs using thermal stabilization and carbonization following a freeze-drying process. Lignin with a foamy and porous microstructure was formed after freeze-drying. Thermal stabilization of the product during the first step prevented agglomerated nanoparticles from forming during the following carbonization process. The addition of KOH affected the size of the LNPs remarkably; the smallest LNPs, 25 nm, were obtained at 15% KOH.

Silver-infused LNPs coated with a cationic polyelectrolyte layer are a green biodegradable substitute to the silver nanoparticles that linger in the environment (Richter *et al.*, 2015). LNPs with biodegradable cores have greater antimicrobial activity and a less negative environmental impact than silver nanoparticles. They can easily neutralize common gram-positive and gram-negative human pathogens, as well as quaternary amine-resistant bacteria, while consuming at least 10 times less silver than conventional silver solutions.

LNPs can also be obtained via physical methods such as ultrasonic/acoustic irradiation, which modifies lignin to obtain LNPs (Gilca *et al.*, 2015). Ultrasound could lead to the development of a range of chemical reactions.

Foams

Del Saz-Orozco *et al.* (2012) found that introducing LNPs to phenolic foams produced LNP-reinforced phenolic foams (LRPFs) with 128% and 174% more compressive modulus and compressive strength, respectively, than unreinforced foams. Interestingly, with the same density, up to 31% of the blowing agent used was saved when producing reinforced foam compared to unreinforced foam. LNP incorporation into foam makes LRPFs competitive with synthetic fiber-reinforced phenolic foam in terms of mechanical strength and, moreover, produces more environmentally friendly foam.

Emulsifiers

Lignin is insoluble in acidic conditions and this is the basic principle of forming lignin particles that can be used as an efficient emulsifier for novel pH-responsive Pickering emulsions (Wei *et al.*, 2012). Chemical emulsifiers or surfactants are essential parts of conventional

emulsion polymerization. They can contaminate the final product and contribute to environmental pollution. The emulsifier prepared through this method provides a cheap, green, and recyclable method for the polymerization of industrial emulsions.

Atom transfer radical polymerization grafting of 2-(diethylamino)ethyl methacrylate of lignin makes it water soluble (Qian *et al.*, 2014b). CO₂ bubbling of the resulting samples that contains lignin disperses lignin in water, but N₂ bubbling precipitates lignin. These features make this lignin a potential green candidate for many applications including as a surfactant for Pickering emulsion. The emulsification/demulsification is repeatable and reversible.

Resins

Da Silva *et al.* (2013) used organosolv lignin to prepare resins (following a classical procedure) that can be used as matrices in composites. The authors found that replacing phenol with organosolv lignin in phenolic-type resins led to a greater resistance to deformation and a higher impact strength composite compared to composites prepared from phenol-formaldehyde resin.

The phenol-substituted organosolv lignin resin can be used in thermosets as phenolic-type resins. Thielemans and Wool (2005) esterified lignin with anhydrides to make it soluble in nonpolar solvents like styrene, which is used in the preparation of thermoset resins. Styrene-soluble lignin can be incorporated in unsaturated thermoset composites.

Ramires *et al.* (2010) produced phenolic-type resins using lignin from organosolv acid hydrolysis without extra purification. Lignin replaced phenol in a lignin-formaldehyde pre-polymer. The resulting composite showed good adhesion in a fiber/matrix interface and good impact strength. For pre-polymer synthesis, lignin was spread in the formaldehyde solution and stirred for 15 min at room temperature. Potassium hydroxide was then added, and, after being stirred for 2 h, the mixture temperature increased to 97°C.

Adhesives

Phenol-formaldehyde (PF) adhesive is applied for high bonding strength and water resistance of bonded plywood. All the components of this adhesive are petrochemical-derived materials (Zhang *et al.*, 2013).

Wood adhesives can be produced from lignin-phenol-formaldehyde (LPF) resin (Khan and Ashraf, 2007). Incorporating up to 50% of lignin in a phenol-formaldehyde adhesive improves adhesive and shear strength, but lignin addition of up to 25% leads to a resin with the same thermal stability as phenol formaldehyde.

Moubarik *et al.* (2013) found that alkaline lignin from bagasse exhibited high reactivity, due to the high activated free ring position content, high molecular weight, and good thermal stability (high thermal decomposition temperature). These characteristics mean this lignin is a great candidate for replacing up to 30% of the phenol in PF resins used in plywood without affecting bond properties. Plywood prepared with this resin has the requirements of interior-grade panels, according to international standard specifications.

Yang *et al.* (2015) prepared LPF resin adhesives using a new formulation build based on accurate investigation of various lignins' functional groups. LPF resin adhesives prepared this way had a similar structure and curing behavior to commercial phenolic resin adhesives. Plywood with high performance and low formaldehyde emissions was produced from LPF resin adhesives (Yang *et al.*, 2015; Moubarik *et al.*, 2013).

Zhang *et al.* (2013) studied the incorporation of lignin from lignocellulosic ethanol production into phenolic resins to prepare LPF adhesives. They found that lignin can substitute phenol by up to 50% in the resulting adhesive and that LPF had a similar structure and higher thermal stability in the initial thermal degradation than PF. The study confirmed that plywood bonded by this adhesive has acceptable performance and preparing LPF is industrially feasible.

Qiao *et al.* (2015) substituted phenol with enzymatic hydrolysis lignin to produce adhesives. Even with the incorporation of up to 50% lignin in PF resin, the adhesive strength did not decrease. However, 60% lignin incorporation lowered adhesive strength, though it was still above the requirements of Chinese first grade plywood. LPF resin exhibited a similar structure but a lower thermal resistance than PF resin.

El Mansouri and Salvadó (2006) studied the characteristics of various types of lignin including kraft, soda-anthraquinone, organosolv, lignosulfonate, and ethanol process lignins for adhesive production. They found that kraft and soda-anthraquinone lignins are more reactive and so more suited to modification than the others and are better raw material candidates for the incorporation into resins, adhesives, and, particularly, phenol-formaldehyde resins. The highest amounts of phenolic hydroxyl are in kraft and soda-anthraquinone; organosolv has a moderate amount. Also, the highest aliphatic hydroxyl content is found in kraft lignin. Better lignins for adhesive production contain more phenolic hydroxyl and aliphatic hydroxyl groups and have a structure with the possibility of forming quinone methide intermediates, unsubstituted 3- or 5-positions on phenolic C9 units, and lower apparent molecular weight. All of these features signal kraft lignin as the best choice for adhesive production.

Nanocomposites

Ma *et al.* (2017) prepared lignin-based poly(acrylic acid) (LBPA)/organo-montmorillonite (OrgMMT) nanocomposites through the copolymerization of lignin-grafted N, N'-methylene-bisacrylamide with acrylic acid. Water absorbency, swelling and

de-swelling rate constants, and absorption capacity of Pb^{2+} of LBPAA were higher than in poly(acrylic acid). LBPAA/OrgMMT has potential applications, including as a fast and feasible way to remove Pb^{2+} ions from polluted wastewater and as a water retention agent with good salt tolerance and low cost.

Plastics and Composites

While the petrochemical-derived plastic market is about 260 million tonnes, around 350,000 tonnes of biodegradable plastic is produced globally; this figure is less than 0.2% of the worldwide plastics market (Song *et al.*, 2009). A short supply of crude oil and its unsustainability as a source for plastic synthesis applications have triggered bioplastics use (Howard, 2002). Rapidly filling landfills, along with water and land pollution issues resulting from excessive use of non-biodegradable petrochemical-based plastics, have also brought increased attention to bioplastics (Song *et al.*, 2009; Howard, 2002; Zheng *et al.*, 2005). Plastics' long-lasting life and degradation period are a concerning environmental burden (Amaral *et al.*, 2012). Plastics' biodegrading depends on the nature of the polyol used (Amaral *et al.*, 2012). Biodegradable polymers from renewable resources have gained considerable attention recently because of their independence on petroleum as well as the negative environmental impacts of nondegraded polymers (Thielemans *et al.*, 2002). Lignin is biodegraded by fungi through oxidation (Yamamoto *et al.*, 1999).

A major problem with the incorporation of lignin into unsaturated polyester and resin is that unmodified lignin is polar and so it is incompatible with styrene. Styrene is used largely in unsaturated polyester resin materials and is nonpolar. However, Thielemans *et al.* (2002) found that a modification with epoxidized soybean oil maleic anhydride remarkably enhanced lignin solubility in liquid resin containing styrene.

One of the most multipurpose three-dimensional polymers is polyurethane (Amaral *et al.*, 2012). It has various applications including as elastomer, foam, adhesive, and paints whose properties can be easily controlled. Its great insulation and mechanical properties make it an excellent candidate in construction, the automotive industry, nautical applications, and equipment manufacturing.

Kubo and Kadla (2004) found that blending up to 25% lignin to poly(ethylene oxide) (PEO) increased the PEO crystalline domain size. Compared to organosolv, Alcell lignin exhibited superior behavior and the associated blends held excellent properties. Moreover, Alcell lignin blends had stronger intermolecular interactions and higher tendency to establish these interactions compared to other lignins (Kubo and Kadla, 2004). Kraft lignin copolymerization with N-isopropylacrylamide (NIPAM) through atom transfer radical polymerization (ATRP) altered the thermal decomposition temperature or thermostability and water solubility of the resulting copolymers (Kim and Kadla, 2010). Lignin can be directly incorporated into other polymers. Blending lignin with natural and synthetic rubber (Kramarova *et al.*, 2007), poly(vinyl alcohol) (PVA) (Fernandes *et al.*, 2006), polyolefins (Cazacu *et al.*, 2004), poly(methyl methacrylate) (PMMA) (Ciemniecki and Glasser, 1988), polyesters (poly(hydroxybutyrate) with up to 40 wt% lignin) (Mousavioun *et al.*, 2010), and poly(ethylene adipate) urethanes (PU) (with up to 10% lignin) (Ignat *et al.*, 2011) improved tensile strength, macromolecular organization, and overall thermal and photochemical stability, as well as anti-oxidant, dynamic mechanical, and bulk and surface properties. However, the initial decomposition temperature of the blend may decrease (Mousavioun *et al.*, 2010). These blends offered enhanced properties at low cost.

Lignin contains both aromatic and aliphatic hydroxyl groups that form urethane linkage effectively by providing reactive sites for isocyanates (da Silva *et al.*, 2009). The downside of urethane production from lignin is that the polyurethanes produced are mostly rigid and brittle because of their highly branched three-dimensional structure. This is the result of lignin structure. Incorporating a linear polyol such as polyethylene glycol (PEG), which is the current practice, can overcome this limitation. Lignin type, content, molecular weight, and polyol type can significantly affect the efficiency of this method. However, lignin's highly branched, variable, and multidimensional structure and composition pose some technical challenges and limitations for composite and plastics applications. A practical and encouraging approach to overcome these challenges is oxypropylation. Oxypropylation releases hydroxyl groups and, particularly, phenolic groups with difficult accessibility and also converts solid lignin to a liquid polyol with an optimal hydroxyl index for polyurethane production (da Silva *et al.*, 2009). Oxypropylation improves the OH functionality of lignin by moving these groups to the ends of the chain of the inserted polyether fragments. It also enhances viscosity and the hydroxyl index and other properties of the polyol (Aniceto *et al.*, 2012). Operational variables such as time, catalyst and propylene oxide amounts, pressure, and temperature should be optimized based on the raw material used and the intended application for the polyol (Aniceto *et al.*, 2012). Compared to non-catalytic pathways, catalytic polymerization was found to produce lignin polyurethane films with consistent properties (Ni and Thring, 2003). However, the ultimate strength, Young's modulus, and crosslink densities of the catalyzed PU films were lower than the ones for the noncatalyzed films. As the NCO/OH molar ratio and lignin content increased, the ultimate strength and Young's modulus improved, but the ultimate strain reduced for both films.

Because of oxypropylation, higher levels of lignin could be incorporated into the PU, and polyol properties were controlled better than when solid lignin was reacted directly with any of diisocyanate, PEG and diisocyanate, or polyether triol and diisocyanate (Li and Ragauskas, 2012).

Lignin from chemical pulping is the major source of lignin-derived plastics (Ragauskas *et al.*, 2014). Lignin structure changes considerably during the pulping process, making it inappropriate for most high-value applications such as material production. However, this lignin would be well suited to plastic production. Different molecular weight, process-

Table 1 Various materials from lignin and their associated production processes

Application	Process	Lignin form/source	Remarks	Refs.
Anode in direct carbon fuel cells (DCFC)	• Anode preparation using a mixture of lignin and electrolytes with a mass ratio of 1 • Dry powder-pressing: loading a mold with the anode powders before pressing at 19.6 MPa for 10 s	Lignosulfonate and kraft lignin	• Direct lignin fuel cell is viable • Hydrophilicity of raw material lignin is critical for fuel cell performance • The Energy conversion of all lignins was the same when pH was adjusted to 10 to alter the lignin structure or add active carbon	(Lima <i>et al.</i> , 2013)
Carbon fibrous mats as anode in lithium ion batteries	• Dispersing lignin and polyethylene oxide into dimethylformamide under magnetic stirring • Heating the suspension • Cooling to room temperature naturally under continuous stirring • Electrospinning • Drying nanofibers • Thermostabilizing in a tube furnace in \atmosphere • Carbonization • Thermal annealing of lignin-derived fused carbon fibrous mats in the presence of urea	Alcell lignin	• The Incorporation of specific proportions of low melting point polymer additives resulted in carbon fibers with good electrochemical performance and lower electrical resistance, comparable to PAN-derived carbon fibers • Doping with nitrogen further improves specific capacity and electrochemical conductivity • Fabrication was both straightforward and economical	(Wang <i>et al.</i> , 2013)
Cathodes	• Dissolving lignin in HClO₄ • Adding same amount of pyrrole to the mixture • Galvanostatic polarization of the substrate electrode • transferring film-covered electrode to pure HClO₄ and • developing quinone functions by cyclic voltammetry	Lignosulfonates from brown liquor	• Polypyrrole /lignin can be used for energy storage and charge transport • Use of the renewable biopolymer should lower the electrode cost and improve safety and nontoxicity • Further developments are needed to enhance capacitance and charge density	(Milczarek and Inganäs, 2012)
Pseudocapacitor used in hybrid electrodes	• Exfoliating graphite oxide in water • Addition of lignin • Addition of hydrazine solution • Placing the resulting stable suspension in an oil bath at 60°C for 12 h to yield a homogeneous dispersion	Softwood sodium lignosulfonate	Hybrid electrodes had: • Good rate and cyclic performances • A maximum capacitance close to the theoretical capacitance	(Kim <i>et al.</i> , 2014)
Nanoporous carbon in supercapacitors	• Immediately transferring lignin extracts placed on alumina crucible to furnace • Purging furnace with argon gas • Increasing temperature step wise to carbonize lignin	Purified kraft lignin, ethanol extracted lignin, and diluted alkali lignin	• Additional activation agents are not required • Lower molecular weight lignins produce porous carbons with higher surface area and fewer defects • Amount of oxygen consumed during carbonization considerably affects porosity	(Jeon <i>et al.</i> , 2015)
Submicron porous carbon fibers for electrode in supercapacitors	• Electrospinning of lignin-ethanol solutions by a co-axial configuration • Thermostabilization under air • Carbonization under inert (N₂) or 1 vol% O₂ under a N₂ atmosphere	Alcell lignin	Power and energy densities comparable or even better than top engineered structures till now	(Berenguer <i>et al.</i> , 2016)
Submicron activated carbon fibers in supercapacitors	• Electrospinning lignin/polyethylene oxide mixture with or without alkaline hydroxides; NaOH/lignin and KOH/lignin • Rolling and placing electrospun precursor fiber mats in an electric furnace • Carbonization under flowing N₂	Alkali lignin with low sulfonate	Supercapacitors from lignin ACFs showed somewhat low equivalent series resistance and exceptional cycling stability, ACFs from alkali Lignin with low sulfonate is superior carbonaceous electrodes for supercapacitors in aqueous electrolytes	(Hu <i>et al.</i> , 2014)

Carbon fiber	● Electrospinning of lignin/ethanol/platinum acetyl acetate and lignin/ethanol (for fibers doped with platinum [ALFPt]) solutions ● Fiber stabilization in air ● Carbonization with a flow of N₂	Alcell lignin	● Diameter and length of fibers are controlled by viscosity, flow, concentration of electrospun solution, or applied voltage (Ruiz-Rosas <i>et al.</i>, 2010) ● Increasing carbonization temperature increases carbon and decreases oxygen content
Activated carbon	● Mixing lignin with the activating reagent and water and kneading ● Drying at 110°C to prepare the impregnated sample ● Carbonization under N₂ flow	Lignin precipitated to form kraft black liquor	● Increasing carbonization temperature increased mesopore volumes (Hayashi <i>et al.</i>, 2000)
Activated carbon for pollution adsorption	● Carbonization in a muffle furnace in N₂ ● Activation carbonized chars under a constant flow of steam	Dewatered black liquor lignin	● Black Liquor lignin can be converted to low-cost activated carbon by physical activation with steam (Fu <i>et al.</i>, 2013) ● Activation Time and temperature and carbonization temperature greatly influenced pore structures of lignin
Activated lignin-chitosan extruded (ALiCE) in dye absorption	● Preparation of lignin-chitosan blend granulating mixture with 20 cm³ of aqueous acetic acid (10% v v⁻¹) extruding the resulting wet mass spherionising to produce pellets ● Drying wet pellets	Alkali low sulfonate content	● Basic Characteristic of ALiCE is lower than its basic characteristic (Albadarin <i>et al.</i>, 2017) ● Dye Removal Efficiency rises slightly with pH increase from 2 to 4, and then the efficiency increases with pH increase from 4 to 7
Acid carbon catalyst for alcohol dehydration	● Impregnation of lignin with aqueous H₃PO₄ at room temperature ● Drying in a vacuum dryer ● Activation under continuous N₂ flow	Alcell lignin	● Increasing the strength and amount of acid sites increased the catalytic activity but did not have a remarkable effect on the value of the dehydration reaction activation energy (Bedia <i>et al.</i>, 2009)
Base carbon catalyst for alcohol dehydrogenation	● Carbonization under a continuous N₂ flow	Sodium-lignosulfonate powder	● 2-propanol, methanol, and ethanol transformed to acetone, formaldehyde, and acetaldehyde, respectively, at atmospheric pressures (García-Mateos <i>et al.</i>, 2017b) ● Conversions were low but selectivities were higher than 80%
Pt-supported submicron carbon fiber electro-catalysts for alcohol electro-oxidation	● Electrospinning in a co-axial configuration and solvent ethanol ● Addition of platinum acetylacetone concentrations to obtain lignin fibers with platinum nanoparticles in one step ● Thermostabilization in air ● Isothermal treatment in furnace under air ● Carbonization with a continuous flow of N₂	Alcell lignin	● The best electrospinning behavior was obtained with a lignin-to-ethanol ratio of 1 (García-Mateos <i>et al.</i>, 2017a) ● Carbon fibers with phosphorus exhibited superior oxidation and electro-oxidation resistance ● Pt-containing carbon fibers can be used as electrodes directly without any binder or promoter
Nanoparticle	● Dissolving lignin in tetrahydrofuran ● Filtering the solution and introducing it into a dialysis bag ● Slow stirring	Kraft process-extracted lignin (LignoBoost)	● Unlike previous method proposed, hazardous chemicals such as acetyl bromide are not needed in this method (Lievonon <i>et al.</i>, 2016) ● Pre-dialysis concentration of lignin is effective on nanoparticles final size

(Continued)

Table 1 Continued

<i>Application</i>	<i>Process</i>	<i>Lignin form/source</i>	<i>Remarks</i>	<i>Refs.</i>
Nanoparticle	● Dissolving lignin in deionised water with KOH ● Solidifying using liquid nitrogen ● Freeze-drying ● Thermal stabilization ● Carbonization under N₂ atmosphere	Protobind 2400 lignin (a by-product of the paper industries)	● Increasing the KOH decreases thermal stabilization yield but increases carbonization yield and decreases overall yield	(Gonugunta <i>et al.</i> , 2012)
Nanoparticle	● Sonicating lignin suspensions for 60 min	Alkali lignins from wheat straw and Sarkanda grass	● Sonication did not result in any significant changes in lignin composition or structure at the intensity applied but depends on the nature of the lignin ● Dominant reactions were cleavage/depolymerization rather than oxidative coupling/polymerization	(Gilca <i>et al.</i> , 2015)
Phenol substituent in phenolic resins for thermosets	● Reacting lignins, potassium hydroxide, glutaraldehyde (a dialdehyde obtained from natural sources) and water ● Stirring ● Acidifying to pH 6 with HCl ● Addition of toluene ● Filtering resins	Organosolv sugar-cane bagasse lignin	● Lignin-glutaraldehyde composites had superior or similar properties to phenol-formaldehyde resin composite	(Da Silva <i>et al.</i> , 2013)
Phenol substituent phenolic-type resins in composites	● Dispersing lignin in the aqueous formaldehyde solution under mechanical stirring ● Addition of potassium hydroxide and mixing ● Heating and stirring ● Neutralizing with concentrated hydrochloric acid	Lignin from organosolv acid hydrolysis of sugarcane bagasse	● Replacing lignin remarkably improved adhesion at the fiber-matrix interface ● Lignocellulosic fiber-reinforced composites exhibited great mechanical properties	(Ramires <i>et al.</i> , 2010)
Phenol substituent in phenol formaldehyde resin	● Transferring lignin cake in a beaker ● Addition of phenol ● Stirring to obtain a homogenous paste ● Addition of formaldehyde solution and methanol ● Addition of sodium hydroxide	Bagasse lignin	● Thermal stability depends on the lignin source ● Incorporation of up to 50% lignin enhances adhesive and shear strength of phenol formaldehyde resins	(Khan and Ashraf, 2007)
Phenol substituent in phenol formaldehyde resin	● Mixing phenol, lignin, and sodium hydroxide aqueous solution ● Cooling ● Resinification	Enzymatic hydrolysis lignin	● Lignin can replace up to 50% phenol in phenol formaldehyde resin without worsening the adhesive strength	(Qiao <i>et al.</i> , 2015)
Incorporation in phenol-formaldehyde (LPF) resin adhesive	● Mixing phenol and lignin ● Addition of NaOH solution ● Heating ● Cooling ● Addition of formaldehyde and NaOH solution in two steps ● Addition of NaOH and urea solution ● Rapid cooling	Corn cob lignin, two kinds of poplar wood lignin, and wheat straw lignin	● Plywood offering high-performance and low-formaldehyde-emission can be prepared with these LPF resin adhesives synthesized based on the new formulation designed following accurate analysis of the active sites in lignin ● The formulation can be adapted to other lignins	(Yang <i>et al.</i> , 2015)

Polyurethane foam	● Mixing lignin, polyol, water (blowing agent), surfactant and catalyst (Kosmos 29) ● Addition of MDI and stirring vigorously	Hardwood organo-solv lignin (HOL) or hardwood kraftlignin (<i>HKL</i>)	● Lignins were not just trapped in the foam-like filler; they were chemically crosslinked (Pan and Saddler, 2013) ● The addition of up to 25%–30% HOL ● Or 19%–23% <i>HKL</i> resulted in foams with acceptable structure and strength ● PUs from HOL offered better strength at the same lignin amount because HEL had a better miscibility with the polyol than <i>HKL</i>
Polyurethane foam	● Drying in a vacuum oven ● Mixing lignin, propylene oxide, and KOH ● Heating, increasing pressure suddenly, and releasing it to produce lignin polyols via oxypropylation ● Mixing polyol with silicone (surfactant) and catalysts (dimethylcyclohexylamine and Mannich base catalyst) ● Addition of pentane (blowing agent) and comonomer methylene diphenyl diisocyanate (MDI) ● Strong stirring till foams are formed	Softwood kraft pine lignin	● Solid lignin modified successfully to liquid polyol with proper hydroxyl index (Li and Ragauskas, 2012) ● Lignin polyol can be used solely for preparation of rigid PU foam without the need to add other polyols or chain extenders ● Rigid PU foam made of lignin polyol offered better mechanical properties than its commercial counterpart
Polyurethane	● Mixing lignin with PEG and THF (solvent) ● Reacting with tolylene 2,4-diisocyanate TDI in the presence of stannous octoate (catalyst) at room temperature	Black liquor lignin	● Poly(ethylene glycol) of molecular weight 200 and a lignin concentration of 50% resulted in polyurethane offering optimum thermomechanical properties (Chahar et al., 2004) ● Shear strength of lignin polyurethane adhesive joints was higher than the commonly used phenol formaldehyde resin prepared using phenolated lignin
Polyurethane film	● Solubilizing lignin and MDI in THF ● Stirring at room temperature till dissolved ● Addition of dibutyltin dilaurate (catalyst) and PEG and stirring under nitrogen	Solvolytic lignin (organosolv)	● Crosslink density of PUs improved with increasing amount of lignin and chain length of PEG (Thring et al., 2004) ● Ultimate strength and Young's modulus of Pus increased with increasing lignin amount till 30 wt% lignin content ● PEG 400 exhibited best results for synthesizing lignin polyurethanes
Polyurethane foam	● Lignin oxypropylation (chain extension) in propylene oxide and in the presence of KOH (oxypropylation catalyst) ● Mixing polyol, surfactant (silicone-based compound for cell stabilization), and catalyst ● (Combination of dimethylcyclohexylamine and Niax A-1) and water (a small amount), stirring vigorously ● Addition of blowing agent (such as pentane for foam formation) and stirring ● Addition of polyisocyanate (MDI) and stirring vigorously	● Soda lignin from Alfa (Stipa tenacissima), organosolv lignin from hardwoods, kraft lignin from softwood, and oxidized organosolv lignin	● Straightforward process (Hamid et al., 2005) ● Polyols have similar characteristics to the conventional materials used in PU preparation ● PUs exhibited good dimensional stability and thermal properties
Slow-release nitrogenous fertilizers	● Oxidative ammoniation (ammonoxidation)	Organosolv kraft, soda, and ASAM (alkaline sulfite anthraquinone-methanol), fermented lignosulfonate from a sodium sulfite process	● Kraft and organosolv lignin resulted in the highest nitrogen contents followed by lignosulfonate (Meier et al., 1994) ● Most influential parameters on ammonoxidation were temperature and oxygen pressure ● 14% nitrogen was fixed in lignins at 150°C and 15 bar

related impurities, and poor ability to be used for further processing retard lignin use for composite applications (Ragauskas *et al.*, 2014).

Lignin offers natural mechanical interlocking within the composite matrix because of its irregular shape, so it connects to the surface and can be used as a surface treatment agent (Thielemans *et al.*, 2002). This interlocking enhances composite properties by improving fiber-matrix strength. Lignin can be incorporated into petroleum-derived composites by/as a toughening agent, network connectivity enhancer, providing extra stiffening units to the matrix, sizing agent between fibers and the matrix, comonomer, toughness enhancer (by prompting plasticity), behaving as a free radical trap to decrease the effects of radical scission during fracture, enhancing flame resistance, increasing biodegradability, improving photo resistance and thermal stability, expanding fatigue lifetime, and green material precursor (Thielemans and Wool, 2005).

Yi *et al.* (2015) synthesized spherical multilayer composite microcapsules, loaded with a healing agent (isophorone diisocyanate), through the polymerization of lignin nanoparticle-stabilized oil-in-water Pickering emulsion templates. The microcapsule showed superb resistance to damage from high temperature, moisture, and solutions. The microcapsule's self-healing coating exhibited a significant anticorrosive and protected the steel plate even after 120 h of immersion in 10 wt% NaCl solution (no corrosion), whereas the control sample was rigorously corroded. Self-healing coating occurs when active agents transferred out of the microcapsules then polymerize, fill the cracks, and prevent corrosive attack. Automatic repairing and promising self-healing properties make these microcapsules strong candidates for industrial and environmental applications.

Concrete

Volume-based lignosulfonates are the dominant admixture used in the construction sector (Plank, 2004). Lignosulfonate is added to concrete with two main aims: as a plasticizer to firm concrete and enhance its pourability, uniformity, flowability, and workability; and to reduce the amount of water required to produce a good workable concrete with a low water-to-cement ratio and high compressive strength. Lignosulfonate reduces the water content by up to only 15%, but synthetic superplasticizers can reduce it by up to 40%. Therefore, for better effects, blending lignosulfonates with synthetic superplasticizers is required. The main reason to use lignosulfonate is its cost competitiveness.

Ammoxidized lignosulfonate prepared via oxidative ammonolysis or ammoxidation (Gargulak *et al.*, 2001) can be used as dispersant in cement or mortar as well as in many other applications including as carbon black, clays, mineral, slurries, and pigments (Syahbirin *et al.*, 2012). Ammoxidized lignosulfonate was found to exhibit remarkably lower entrapped air and retardation than its corresponding lignosulfonate before ammoxidation.

Other Applications

Lignin has other potential applications that need further investigation, for instance as vegetation proxies in lake sediment cores and natural waters (Heidke *et al.*, 2018), molecular marker of plant carbon turnover (Panettieri *et al.*, 2017), etc. Meier *et al.* (1993) found that mixtures of lignosulfonate with fertilizer improved nitrogen recovery and fertilizer efficiency. Acar *et al.* (1991) found that calcium lignosulfonate used as a binder in animal feed pellets offered better pellet quality, excessive dietary energy level, and helped in fat deposition. Chemical pulping lignin dominates the commercial market as an additive in cement, drilling fluid in oil recovery, and dust suppression (Ragauskas *et al.*, 2014; Strassberger *et al.*, 2014).

Table 1 shows various macromolecule products from lignin and the associated process characteristics.

Conclusion

This article reviewed different possible approaches to lignin-based higher value chemical and material production. Considering increased lignin production resulting from developments in cellulosic biorefineries and ethanol production plants, it is not reasonable to just burn lignin as a waste fuel while making use of lignin brings about profit. Benefiting from its polymerized multi-dimensional structure, lignin can be converted to various polymeric and high performance materials. There are many potential applications of lignin to value-added use through the processes and to the materials described in this article. However, to achieve the best results, all of the following need to be efficient and optimized: lignin isolation from biomass, lignin degradation, value-added production pathways, and the purification of final products.

Introduction

Improved economy, technological advancement and their easy accessibility, rapid growth in world population and increase in standards of living have led to a substantial rise in energy demand. Number of buildings and their energy consumption is rapidly increasing. There are approximately 1.6 billion installed air conditioning equipment all over the world, which collectively account almost 20% of the total energy consumption (IEA, 2018). The main objectives of air conditioner are to provide human thermal comfort and desirable hygienic indoor air quality. Indoor environmental conditions significantly affect human health and work efficiency. It is controlled by the regulation of temperature, humidity and purity of air within prescribed limits. In conventional air conditioners, thermal comfort is attained by cooling the outside air below its dew point value and subsequently, air is reheated to desired supply condition. Enormous amount of energy is expended in overcooling and reheating of air which escalates the overall running cost of the system. Wet surfaces created by condensation of air act as a breeding ground for fungi and bacteria, which severely influences human health. Moreover, the harmful gases (CFC, HCFC and HC) released from the air conditioner causes environmental threats like ozone layer depletion and/or global warming. Although vapor compression is the most sophisticated and well developed technology, it does not handle moisture reduction process in an energy efficient way. Therefore, worldwide there is a need to developed proficient air conditioning devices which can handle sensible and latent load efficiently. Use and development of sustainable and eco-friendly HVAC (heating ventilation and air conditioning) systems such as solar air conditioning, geothermal heat pump, absorption and adsorption based desiccant cooling systems can considerably normalize the limitations of conventional air conditioners.

Need for Sustainable and Renewable Energy Based Air Conditioning

Despite the fact that we have made significant progress in all fields of science but still our primary energy demand is met through fossil fuels. The energy production through fossil fuels has created many environmental concerns such as oil spills, acid rain, acid rain, climate change, global warming etc. Fig. 1 shows the primary energy consumption in different sectors. Major portion of the electricity consumed in building (residential and commercial) is required for heating and cooling. The energy consumed in HVAC is approximately 50% of the total building energy in developed countries (Pérez-Lombard *et al.*, 2008). It is estimated that worldwide energy intake for cooling buildings will increase to 4000 TWh (Terawatt-hour) in the year 2050 (Mucke *et al.*, 2016). Therefore, to alleviate the consumption of non-renewable sources of energy in HVAC – the development of efficient heating and cooling systems running primarily through renewable and sustainable energy is the need of the hour. Renewable energy is generated through sources that naturally replenished themselves and never get exhausted. The most common sources are hydroelectricity, solar energy, wind energy, wave power, geothermal energy, and tidal power. As depicted from the Fig. 2 – the interest in renewable energy is growing rapidly. Renewable has many advantages; it can help in combatting energy security and climate change issues together. Hydro, tidal and solar create zero air pollution, while the emission from biomass and geothermal is minimum. Downside of renewable energy – it is difficult to generate large-scale power from renewable sources same as fossil fuels. Building dams and wind farms can disrupt wildlife and ecological balance. The generation of solar energy is intermittent in nature as it is available during sunshine. Sustainable and renewable sources of energy offer a promising alternative to greenhouse gas emission from fossil fuels. As the technology advances; renewable energy will become more accessible, affordable and efficient.

Conventional Air-Conditioning System

The modern air conditioning system based on vapor compression (VC) technology is the most versatile and extensively used system to achieve comfortable indoor air quality. The basic elements of vapor compression system are compressor, condenser, evaporator, and throttling valve. These systems work in a closed cycle, where a fixed amount of working fluid (refrigerant) continuously flows in a closed loop of components. The Fig. 3 shows the simple vapor compression system. The compressor works between the evaporator and condenser pressure. Compressor converts the low pressure and low temperature saturated vapor refrigerant into high temperature superheated refrigerant. This superheated refrigerant at high pressure and temperature enters the condenser, rejecting the heat of condensation to ambient air/cooling water (produced through cooling tower) and subsequently it is converted in to liquid form. The liquid refrigerant at high pressure is transformed to a low pressure liquid-vapor refrigerant by the throttling valve. Then, the low temperature refrigerant at the inlet of evaporator undergoes a phase change by absorbing heat

Fig. 1 Primary energy consumption in different sectors (<https://www.iea.org/buildings>).

Fig. 2 Share of global electricity generation by fuel (<http://www.bp.com/globalcorporateenergy-economic-statistical-review-of-world-energy>).

Fig. 3 Vapor compression system.

from the conditioned space. The vapor refrigerant then enters the compressor to complete the thermodynamic cycle. The vapor compression system can be used for both heating and cooling the conditioned space. Fig. 4 shows the typical room air conditioner. The cooling capacity and energy requirement of the air conditioning system depends on the room latent and sensible load. The cooling and heating effect is produced in a cyclic manner through evaporation and condensation of refrigerant in evaporator and condenser. Compressor is the only work consuming element in the VC system. The heat rejected from condenser represents the heating load while the heat absorbed by evaporator represents cooling load.

Fig. 4 Typical room air conditioner.

Fig. 5 Solar heat pump.

Sustainable Air Conditioning

The thermal and economic performance of compression heat pump can be elevated by using solar thermal collector (Mohanraj *et al.*, 2018). The combination of solar system with heat pump is an emerging alternative for building space heating.

Solar Heat Pump

Solar heat pump is the integration of vapor compression heat pump and solar thermal collectors (Fig. 5). The heat pump includes basic elements such as condenser, expansion valve, evaporator (intermediate heat exchanger). The heat pump includes basic elements such as condenser, expansion valve, evaporator (intermediate heat exchanger). The fundamental function of solar thermal collector is to absorb the solar radiation (heat) and transfer it to the working fluid flowing inside the pipes attached to the absorber plate. The heat energy absorbed by the working fluid is transferred to the heat pump fluid via indirect intermediate heat exchanger. The heat pump uses the condenser heat of the system to maintain the temperature of the space in warm state. The commonly used working fluid in solar system is either water or glycol and heat pump uses any HCFC/HFC refrigerant such as R-134a. Advantage of combining solar system with heat pump is to improve the performance of sub system which eventually increases the performance of solar heat pump as a whole. The system works in the presence of solar radiation; hence during night hours some additional in absence of it, some auxiliary heat exchanger auxiliary heating medium (electrical heating or condenser heat) is used. Emam Hassanien *et al.* (2018) investigated the viability of solar heat pump for greenhouse heating in China. They showed that system can provide more than 35% of the heating requirement for heating greenhouse. Bellos and Tzivanidis (2017) compared the thermo-economic performance of conventional heat pump with solar heat pump. They concluded that electricity saving between 30% and 40% is possible through solar heat pump.

Direct-Expansion Solar Heat Pump

Sporn and Ambrose in 1955 introduced the concept direct expansion solar heat pump (DXSHP). With high potentials for cooling, heating, drying, and air conditioning application; the investigation on DXSHP has progressed in the past decade. Direct expansion

Fig. 6 Direct expansion solar heat pump.

heat pump if adapted for cold climatic conditions allows sustainable space heating and hot water production simultaneously. In this type of configuration, usage of high and low intensity insolation for heating requirement is made viable via direct heating and expansion of refrigerant in the solar collector-evaporator. **Fig. 6** shows the schematic diagram of DXSHP. The solar module can be a simple solar thermal collector or a photovoltaic-thermal (PVT) module. The system performance is affected by intensity of insolation, ambient temperature, compressor speed and type of refrigerant (Kong *et al.*, 2018). DXSHP is largely investigated for water heating application followed by space heating and very few investigations is reported for space cooling (Omojaro and Breitkopf, 2013). The advantages of DXSHP over conventional heat pump are as follows: (1) Superior thermodynamic performance. (2) Reduction in corrosion problem of solar collector. (3) Longer life of solar collector. (4) Lower system cost.

Solar Photovoltaic-Thermal Heat Pump

The concept of solar photovoltaic-thermal heat pump was initiated by Kern and Russell in 1978. Many research studies had investigated photovoltaic thermal hybrid solar collectors (Charalambous *et al.*, 2007; Emmi *et al.*, 2017; Noro and Lazzarin, 2018). The solar photovoltaic thermal collectors are devices, which simultaneously convert solar radiation into thermal energy and electrical energy. The collector comprises a photovoltaic module with absorber plate affixed to the back of PV module. The absorber plate maintains temperature of photovoltaic module by absorbing thermal energy as well as heat released during conversion of solar energy into electrical energy. The two different system i.e., solar heat pump and photovoltaic thermal hybrid solar collector are integrated to form solar photovoltaic thermal heat pump. In this technology evaporator of heat pump and solar photovoltaic thermal collector are combined in a single unit. **Fig. 7** shows the schematic diagram of solar photovoltaic thermal heat pump. The PV thermal collector simultaneously provides heat source and electricity to evaporator and compressor. The efficiency of photovoltaic thermal collector increases due to absorption of heat from photovoltaic module. Huide *et al.* (2017) mathematically and experimentally compared the performance of photovoltaic system, solar thermal collector and hybrid photovoltaic thermal collector for different location in China. The findings indicated that hybrid system has the greatest energy saving potential for urban areas as compared to other solar systems and for rural areas depending on the area of installation the hybrid or photovoltaic system can be the most optimal option.

Solar-Geothermal Hybrid Heat Pump

Solar and geothermal energy both are widely used renewable source of energy. Both are cleaner and sustainable energy that can be used to avoid adverse environmental impacts caused by burning fossil fuels. When the solar radiation is sufficient the heating system absorbs heat only from the solar collector otherwise some auxiliary heating source such as geothermal energy can be used. Solar geothermal heat pump technology integrates solar collector and geothermal heat exchanger with a heat pump system. The solar collector and geothermal heat exchanger can be connected either in series or parallel configuration. The sources of energy for heating are solar and geothermal. **Fig. 8** illustrates the line diagram of solar geothermal hybrid heat pump. When the temperature rise of water in the solar collector is not sufficient, it is sent to geothermal heat exchanger to absorb the extra heat. The refrigerant exchanges energy with the hot water through the intermediate heat exchanger. The series combination is more efficient as compared to parallel configuration (Mohanraj *et al.*, 2018). The combination of geothermal heat exchanger with solar collector reduces the overall size of geothermal heat exchanger. The amount of solar radiation and temperature of ground have significant impact on the compressor work. A performance simulation study on solar-geothermal heat pump for residential heating application under different operating conditions was carried out by Kim *et al.* (2013). The result showed that with increase in ground temperature from 11°C to 19°C, the pressure ratio of compressor decreases from 3 to 2.5 and maximum COP reaches to 2.81.

Solar Thermoelectric Air Conditioning System

The thermoelectric cooling technology was invented by Peltier in 1834. The principle of thermoelectric cooling is based on Peltier effect which is also known as reverse of Seebeck effect. In a circuit consisting of two different metals, an emf (Electromotive force)

Fig. 7 Solar photovoltaic thermal collector heat pump.

Fig. 8 Solar geothermal heat pump.

Fig. 9 Thermoelectric air conditioning system.

is generated, when two junctions are maintained at different temperatures. This effect is known as thermoelectric effect or Seebeck effect. The magnitude of emf generated depends on the type of material and the temperature maintained at two different junctions. The two junctions can act as a source of absorption and rejection of energy. Although the thermal efficiency of solar thermoelectric air conditioning system is low, the system is quite popular because of simple design, low space requirement, and low cost (Liu *et al.*, 2015b). Moreover, as the system is not having any mechanical parts; it is free from wear, tear and noise problems. A typical thermoelectric module comprises of a stack of P-type and N-type semiconductor pellets sandwiched between ceramic substrates. The P-N pellets are usually designed to connect electrically in series and thermally in parallel. When current is supplied to module, charge carrier (positive and negative) in the pellet stack absorbs thermal energy from one side of substrate surface and releases it to opposite side. Fig. 9 shows the schematic of thermoelectric air conditioning. One surface becomes cold, where heat energy is absorbed and the opposite surface becomes hot, where heat energy is released. The photovoltaic (PV) collector can be used directly to power the thermoelectric module, which can largely reduce the cost of the overall system. In the daytime, the solar panel supplies energy to thermoelectric air conditioner through conversion of thermal energy into electrical energy by photovoltaic module. If the power supplied exceeds, it can be stored in a battery in addition to driving the solar thermoelectric module. During night or cloudy day the electrical energy from the battery can be used to power the thermoelectric module.

Vapor Absorption System

Vapor compression system (VCS) is electrical energy driven system. It is not feasible to use VCS, where there is shortage of electricity. In such conditions, an alternative to VCS Vapor absorption systems (VAS) can be used. VAS are heat driven systems, they require major energy as heat. They are gradually becoming more popular as heat can be supplied through various sources including the renewable as well as waste heat available from the industry.

Vapor Absorption Air Conditioning System

The working components of VAS are similar to VCS. The compressor in VAS is replaced by absorber, pump and regenerator. Fig. 10 shows the working of VAS system. Low temperature and low pressure refrigerant in gaseous form is driven towards the absorber due to negative pressure gradient. The absorber vessel is filled absorbent solution, which has high affinity to absorb the refrigerant. The absorbent absorbs the refrigerant vapor and heat of vaporization is liberated. The liquid solution is then pumped to the regenerator. The solution rich in refrigerant is heated in the regenerator for separation of the absorbed refrigerant in gaseous form

Fig. 10 Vapor absorption system.

out of rich solution. Then, the gaseous refrigerant is condensed in the condenser to liquid form by rejecting heat to the environment (external sink). Finally, the refrigerant is throttled from condenser pressure to evaporator pressure inside the expansion valve. In regenerator, hot and strong absorbent solution is throttled back to the absorber side. Same pressure is maintained in the condenser and regenerator and in evaporator and absorber. Energy consuming devices in VAS are regenerator and liquid pump. The mechanical work required for running the liquid pump is almost negligible in comparison to compressor of VCS system. Although VAS system is promising alternative to VCS, yet on account of poor COP and bulky size – the technology could not enjoy the commercial success similar to VCS. The thermal efficiency of VABS can be improved by employing efficient solar collector to drive regenerator of VABS (Kojok *et al.*, 2016).

Solar Vapor Absorption System

Vapor absorption system driven by solar energy had attracted the interested of many researchers (Siddiqui and Said, 2015; Sarbu and Dorca, 2018; Shirazi *et al.*, 2018). The pioneering work in solar absorption system was started by Farber at the University of Florida. Fig. 11 illustrates the vapor absorption cycle powered by solar energy. Heat generated in the solar collector elevates the temperature of weak solution (inside regenerator) large enough to lead the separation of refrigerant vapor. The superheated refrigerant gas at high temperature and pressure is condensed in the condenser. High pressure condensate temperature is reduced through throttling process and subsequently it produces cooling effect through evaporation of liquid portion of the refrigerant in to evaporator. Vapor generated in the evaporator is absorbed inside the absorber due to presence of low pressure absorbent solution. Additional devices such as rectifier may be required for effective separation of pure refrigerant inside the regenerator in case the boiling temperatures of refrigerant and absorbent solution are close. Lithium bromide–water (LiBr–H₂O) and water–ammonia (H₂O–NH₃) are the two most-commonly used refrigerant–absorbent pair in the vapor absorption system. In Lithium bromide–water (LiBr–H₂O) pair; water is a refrigerant and Lithium bromide solution is an absorbent, whereas in case of water–ammonia (H₂O–NH₃) pair; water is an absorbent and ammonia act as a refrigerant. The H₂O–NH₃ generally used for large scale cold storage, whereas LiBr–H₂O is used for air conditioning application – otherwise LiBr salt will crystallize. Regeneration temperature required for water–ammonia (H₂O–NH₃) is higher and its COP is lower as compared to Lithium bromide–water (LiBr–H₂O) working fluid pair (Li and Sumathy, 2000).

Geothermal Vapor Absorption System

In vapor absorption system, the desired cooling effect is obtained by coupling two separate working fluids, these fluids are separated inside the regenerator using high thermal energy. The energy needed for their separation can be supplied through different sources i.e., electric heater, solar collector, and geothermal system. Geothermal energy in stand-alone mode can be used for both cooling and heating applications but is more economical in case used for heating application. The temperature required for regeneration in single stage vapor absorption cooling system is rated around 115°C (Yilmaz, 2017). Therefore, the prospect of combining heat driven vapor absorption cooling system with geothermal application is enormous. Using geothermal energy in place of some fossil fuel burning or even solar energy for regeneration purpose helps in reducing greenhouse gas emission as geothermal energy is available for 24 h on continuous basis. In the evaporator the liquid-vapor refrigerant absorbs the heat from the conditioned space and converts into vapor form, these refrigerant vapors are sent to absorber where it is mixed with cold absorbent, causing the refrigerant to liquefy. The solution rich in refrigerant and absorbent is pumped to the regenerator. In regenerator the solution is heated through geothermal fluid, which helps the refrigerant to evaporate and separate itself from absorbent solution. The vapors are passed through rectifier which only allows vapor to pass to the condenser, in condenser the

Fig. 11 Solar vapor absorption system.

solution is again condensed and sent to expansion device. From the regenerator, the weak solution is expanded and sent to absorber again. The low temperature refrigerant in the evaporator produces the cooling effect by absorbing heat from the conditioned space. Fig. 12 shows the geothermal vapor absorption system.

Desiccant System

The desiccant cooling technology is another promising alternative to conventional air conditioners. Desiccant cooling system is an air conditioning method, which operates with ecofriendly working fluid. They are also known as open absorption system thus they

Fig. 12 Geothermal vapor absorption system.

permits the use of water as the refrigerant. They can help in solving technical limitations of both vapor compression and vapor absorption system. They cannot suffice sensible heat demand of the air conditioning system thus needs to be coupled with either with VCS, VAS, geothermal or evaporative cooling system. Low thermal energy sources such as waste energy at low temperature, flat plate solar thermal collectors can be used to regenerate the desiccant material. Desiccants are hygroscopic materials, which have natural affinity to absorb moisture from the air. They are classified as solid desiccant or liquid desiccant on the basis of physical state. The physical process governing the moisture removal is different for both the desiccants. In the case of a solid desiccant system, moisture reduction is obtained by physical entrapment of water vapor in the micro porous structure of the desiccant (adsorption). On the contrary, the moisture is absorbed at interface of the liquid solution (absorption) in the liquid desiccant system.

Solid Desiccant Air Conditioning System

The concept of solid desiccant dehumidification was proposed in 1935 by Hausen. Solid desiccant materials are impregnated, embedded or coated over a lightweight honeycomb shaped matrix called a desiccant wheel. This honeycomb structure has a very large surface area, which is coated with adsorbent material. The adsorbent material is full of tiny holes that further enhance the surface area. The most vital component of the solid desiccant system is the desiccant wheel which continuously rotates at low speed. **Fig. 13** shows a typical solid desiccant wheel. The desiccant wheel consists of two section adsorption side and regeneration side. The most commonly used solid desiccant materials are silica gels, zeolites, synthetic zeolites, activated alumina, carbons, and synthetic polymers (Giampieri *et al.*, 2018). The desiccant wheel creates a low vapor pressure on the adsorption side leading to

Fig. 13 Solid desiccant wheel.

Fig. 14 Solid desiccant system.

dehumidification of process air and on the regeneration side hot air is used for reactivation of solid desiccant matrix. **Fig. 14** represents the working of commonly used solid desiccant dehumidification system. The desiccant wheel initially lowers the moisture content of the inlet air. Air temperature increases during the dehumidification process. The warm and dry air is cooled with help of energy recovery wheel transferring heat from hot air side to exhaust air side and subsequent cooling in evaporative cooling system. The conditioned air is then supplied to the space requiring air-conditioning. The return air from the conditioned space on the exhaust side passes through energy recovery wheel to exchange a part of heat with the supply air. The exhaust air still needs more thermal energy (shown through electrical heating) before supplied to the regeneration side. The temperature of regeneration air depends on the demand of cooling. Liquid desiccant systems have following advantages over solid desiccant system: (1) It is quite simple to obtain isothermal dehumidification and regeneration. (2) The liquid desiccant solutions have strong thermal storage capability. (3) The liquid desiccant can sterilize many organic impurities present in air apart of reducing dust particles. (4) Liquid desiccant system requires lower regeneration temperature. On commercial front solid desiccant system has emerged as successful commodity but liquid desiccant systems are still struggling with technical limitations of corrosion and carryover problems.

Solar Solid Desiccant Cooling System

The solar solid desiccant cooling system is the integration of solar hot water system with solid desiccant dehumidification system. The hot water generated through the solar system transfer heats up return air through some air-liquid heat exchanger such as fin-tube heat exchanger. Coupling of solar heat certainly helps in reducing the external thermal energy demand but the requirement of alternate heating source cannot be entirely exterminated considering intermittent availability of solar energy and large variation in solar irradiance. **Fig. 15** shows the typical solar solid desiccant system. Depending on the requirement of regeneration temperature advance concentrated solar thermal panels such as parabolic trough and linear fresnel systems can be used. The regeneration air heated from flat plate solar collector ([Merabti et al., 2017](#)) vaporizes the water molecules absorbed in the pores of the desiccant material.

Liquid Desiccant System

Fig. 16 shows the schematic diagram of a simple liquid desiccant system (LDS). In absorber cooled and concentrated desiccant enters from the top of tower while air may flow from cross, counter or same direction. The process air is dehumidified due to

Fig. 15 Solar solid desiccant system.

Fig. 16 Liquid desiccant system.

difference of vapor pressure between moist air and the surface of desiccant solution. Heat is released during moisture transfer process, which increases the temperature of air as well as liquid desiccant both. The solution becomes diluted due to absorption of moisture from the process air. Before entering the regenerator, the weak solution is first passed through a solution-solution heat exchanger so that its temperature can be increased using hot solution coming out of the regenerator unit. The solution is further heated by a heating coil to the required regeneration temperature. The heating of desiccant solution increases its vapor pressure. The solution strips excess moisture to another stream of air passed inside the regenerator. The concentrated solution is reverted back towards the absorber side for completion of the cycle. It is cooled first inside the solution to solution heat exchanger through the diluted solution and then passed through the cooler before being sent to the absorber. Cooling of concentrated solution helps in reducing the vapor pressure of it, which ensures effective dehumidification of process air inside the absorber. The physics of the

Fig. 17 Psychrometry of air in LDS.

both absorption and regeneration process is same except the purpose. **Fig. 17** shows the psychrometric chart of air as it flows through the absorber and regenerator. Process 1–2 represent the air state transformation inside the absorber; similarly process 1–3 represent the air state transformation inside the regenerator. The temperature of air increases as the result of heat liberated during dehumidification process, whereas the air temperature during regeneration process increases due to sensible heating of air through hot liquid desiccant solution. The absorber and regenerator are chemical reactors – conventional designs of chemical towers are: packed, spray and falling film reactors. Packed bed design is suitable for large capacity systems whereas falling film is suitable for small capacity residential systems. In general metallic surfaces are used as packings or solid surface in case of packed tower or falling film tower respectively. Recently, interest in plastics has increased (Liu *et al.*, 2015a; Patil *et al.*, 2016) to avoid corrosion problem of metallic surface. The use of plastic can offer promising future for the development of long life liquid desiccant air conditioning system.

Solar Liquid Desiccant Systems

The temperature required for regeneration is comparatively low in liquid desiccant systems compared to closed vapor absorption system or solid desiccant system. Solar energy can be most effectively utilized in desiccant solution. Liquid desiccant can be heated either directly or indirectly through solar energy. **Fig. 18** shows the basic indirect solar liquid desiccant system. Different types of solar collectors: the flat plate solar collector, evacuated tube, and parabolic collector can be used for that purpose. A 16 kW prototype of solar desiccant system was developed and tested by Gommed and Grossman (2007). The system consisted of packed bed absorber (dehumidifier), regenerator (desorber), heat exchangers, and a flat plate solar collector. The system had a thermal COP of 0.8, and solar collector was utilized for providing the thermal energy for heating the solution. Audah *et al.* (2011) tested the feasibility of liquid desiccant powered by solar energy to produce fresh water and thermal comfort together for the city of Beirut. Direct solar regenerator is the simplest method of removing water vapor from the liquid desiccant solution. The desiccant solution is directly heated in the solar collector, releasing water vapor from the weak solution. The scavenging air then eliminates the water vapor by absorbing it along the collector plate. Kabeel (2005) experimentally compared the performance of cross forced air flow solar regeneration collector with free convection regenerator. They concluded that performance of free convection solar regenerator is low as compared to cross forced convection regenerator. The direct regeneration method is economical as it eliminates the need of separate regeneration tower; further electric heater can be used after solar collector to increase the system performance. The greatest setback is the heavy dependence of system on weather conditions.

Liquid Desiccant-Based Evaporative Cooling

Evaporative cooling based liquid desiccant system is suitable for comfort applications. The evaporative cooling is simple and passive cooling technology, where cooling is provided through evaporation of water. In this system, liquid desiccant and evaporative cooler are combined together to supply cool and dehumidified air at desired level. These systems offer promising application for achieving thermal comfort especially in hot and humid region. The desiccant system handles the latent load, whereas evaporative cooler facilitates in achieving desired sensible cooling. Energy is mainly consumed to drive the fans, water pump and to regenerate the liquid desiccant. Renewable sources like solar collector, geothermal heat exchanger, biomass etc. can provide the required energy for regeneration purpose. Evaporative cooling systems are classified as direct (swamp) evaporative systems, indirect evaporative systems and regenerative evaporative cooling systems. In the direct evaporative cooling system cooling produced through evaporation of air is directly transferred to the process air, whereas in the indirect system the cooling is

Fig. 18 Solar liquid desiccant system.

transferred to the process air indirectly thus humidity content of process air remains constant unlike direct evaporative cooling system. Regenerative evaporative cooler consists of series of multiple pairs of wet and dry channels separated by a heat transfer medium in a compact heat and mass exchanger. The air in the dry channel is cooled close to its dew point value as water evaporates in the multiple wet channels. [Fig. 19](#) illustrates the typical evaporative cooling coupled liquid desiccant system. The potential combination evaporative cooling principle with desiccant system had been investigated by many researchers ([Jain et al., 1994](#); [Kumar et al., 2009](#); [Buker et al., 2015](#)).

Affordable and Promising-Liquid Desiccant Based Cooling System

Desiccant based evaporative cooling system capable of providing sensible cooling but at the cost of over dried air than required humidity level. Absorber needs to dehumidify the process air than desired levels that lowers the efficiency of overall system. The vapor compression systems are best option to handle the sensible cooling requirement. The combination of vapor compression system and liquid desiccant system is usually known as hybrid liquid desiccant systems. The [Fig. 20](#) shows the working of simple hybrid liquid desiccant system. The sensible cooling of the air can be carried out before of the dehumidification process inside the absorber or after of that utilizing evaporation of refrigerant vapor inside the evaporator of VCS. In the past, integration of liquid desiccant with VCS has been largely studied by [Dai et al. \(2001\)](#), [Mucke et al. \(2016\)](#) and [Su and Zhang \(2017\)](#). The hybrid cycle

Fig. 20 Hybrid liquid desiccant system.

Solar energy has a promising application in hybrid liquid desiccant system. In the past decade, the notion of solar hybrid liquid desiccant system is getting more and more attention. The use of solar energy is economical as it obliterates the use of auxiliary thermal heater in hybrid liquid desiccant system. The performance of hybrid solar system consisting of conventional vapor compression heat pump and liquid desiccant air conditioning system was analyzed by [Sick et al. \(1988\)](#). Simulation study using TRNSYS was carried out on different operation mode of the hybrid system including regeneration through solar energy. The author concluded that system operated with solar flat plate collectors for regeneration had the lowest operating cost. [Khalid Ahmed et al. \(1997\)](#) simulated open vapor absorption cycle integrated with liquid desiccant with partly close-open solar collector for regenerating the solution. Maximum COP of 1.25 was obtained under hot and humid conditions with this system.

Advantages of HLDAC System

(1) HLDAC system offers more energy saving and enhancement in COP as compared to standalone VCS (2) Moreover, renewable energy like solar and geothermal can be used effectively in HLDAC system (3) The condenser heat eliminates the need of auxiliary thermal heater when it is used for heating the solution (4) Hybrid liquid desiccant air conditioning reduces the power intake by achieving thermal comfort by a smaller VCS (5) This system is economical where humidity and cost of electricity is high.

Other Emerging Technologies

Application of Phase Change Material (PCM) in Air Conditioning

PCMs are group of material which have inherent capability to store and release large amount of thermal energy during phase change. There are varieties of PCMs of different materials (organic, inorganic and eutectic mixture) meant for different applications. The endothermic and exothermic phase change process can be utilized effectively to provide heating and cooling effect. In PCM thermal energy storage approach, during night cold (low temperature) energy is stored by solidifying the PCM and in the next daytime the

Fig. 21 PCM assisted air conditioning system.

Fig. 22 Radiative cooling system.

stored energy is utilized for cooling purpose. [Fig. 21](#) shows the application of PCM to air conditioning system. Various researches investigated the concept of PCM to improve the cooling efficiencies of air conditioner. [Stritih and Butala \(2010\)](#) demonstrated an experimental study using paraffin to cool air at daytime and to store cold energy at night time. [Said and Hassan \(2019\)](#) experimentally investigated the integration of PCM plates with the condenser of AC unit. The result indicated that the performance of AC unit with PCM plates is superior as compared to AC unit without PCM plates. They reported that power reduction of 11.2% was achieved with PCM plates. Energy and economic analysis of air conditioning with PCM was carried out with by [Chaiyat \(2015\)](#). They concluded that electric consumption of air conditioner could be reduced to 3.09 (kilowatt-hour/day), with a cost saving of 170 USD/y.

Radiative Cooling

With increase in cooling demand; the greenhouse gas emissions accredited to HVAC industry will increase. Especially the cooling demand is expected to increase rapidly overlooking the wide visualized influence of global warming. There exit an amazing opportunity to augment the efficiency of cooling system by 10%–20%, which could have enormous impact on our greenhouse gas emission both today and later this century. The concept of radiative cooling is not new, it had been used centuries ago for production of ice in desert climate. [Fig. 22](#) shows the commonly used radiative cooling technology. All matter on earth emits thermal radiation, a part of which is absorbed by the earth atmosphere and the rest is reflected back. At certain wavelength in particular between eight to thirteen microns; the earth atmosphere acts as transparent window. Through this window, body is cooled by emitting heat in the outer cold space which is considered as infinite thermal reservoir at atmospheric temperature. For instances, frost and dew drops in morning are direct consequences of radiative cooling. Radiative cooling is a free and passive cooling technology to dissipate heat to the outer cold space which is a natural heat sink. Nighttime radiative cooling been widely investigated since 1918 with both organic and inorganic materials of different infrared-emissivity. Recently, [Zhao et al. \(2017\)](#) proposed a combined photovoltaic-radiative cooling system for buildings that can produce electricity during daytime through photovoltaic conversion and provide cooling effect in night via radiative cooling. [Hu et al. \(2018\)](#) designed a practical scale hybrid

system consisting of photovoltaic-photothermal-radiative cooling collector. The integrated system was capable of providing heat and electricity during day time and cooling energy at nighttime. The overall cooling energy obtained at typical clear night was 2.90 MJ with electrical/thermal efficiency in the range of 40.4% and 56.9%. Daytime radiative cooling has not been investigated widely because of Sun's heating. In the year 2014, Raman *et al.* (2014) designed a rooftop nanophotonic radiative cooler. The difference between the atmospheric temperature and nanophotonic cooler was 5°C right at the peak sunlight of 900 W/m². The authors designed a novel nano structure that reflected almost all the daytime sunlight while emitting maximum radiation in the range of 8–13 µm. The potential application of radiative cooling technology is promising for improving the energy efficiency of existing systems.

Conclusion

The chapter gives a brief description of renewable energy application in air conditioning system with few references to the current and past study. It is urgent need to increase the use of renewable energy in all sorts of air conditioning systems (both conventional and non-conventional). The main motivation of using renewable energy technologies is to cut down greenhouse gas emission and emission of other harmful refrigerant in to our environment. Many research findings have indicated that the combination of solar and geothermal energy decreases the energy intake and size of the geothermal heat exchanger. The solar assisted heat pumps have a promising future as it alleviates the energy load on heat pumps. The low-grade energy from the solar collector provides an effective source to match the heating load of the regenerator in liquid desiccant system. The solar assisted hybrid desiccant system has a much wider scope to provide comfortable indoor air quality at optimum energy requirements. Emerging technologies such as passive radiative cooling and phase change material are promising for achieving thermal comfort. Sustainable uses of renewable energy will not only curb down the CO₂ emissions but will also safeguard the high-grade source energy for future need. The use of renewable energy is very much essential for developed and developing country to sustain their energy demands.

Toward Reclamation of Fibrous Waste Stream Materials

Marlann M Patterson, University of Wisconsin – Stout, Menomonie, WI, United States

© 2020 Elsevier Inc. All rights reserved.

Introduction

Indirect materials (those not in final product, *i.e.*, waste) may have properties to function as direct materials for other applications. Companies pay millions to produce a more efficient method of production by minimizing cost and waste. Decreasing waste and minimizing cost has numerous benefits like increased savings for consumer/producer as well as environmental benefits. Fibrous materials are sent to landfills, taking up space and leading to potential hazards, particularly in residential areas (Al-Yaqout and Hamoda, 2002). Problems with waste sites arise many years after they have been filled, covered, and built upon (Emberton and Parker, 1987). Much of the United States' waste is transported across oceans to third world countries where land costs less and the people living nearby have little to no ability to voice their opinion based on education, income, or social standing.

Researchers have been investigating numerous waste products to replace high cost insulation. Thousands of different waste materials have unknown insulating properties that go silently into landfills. One research project measures thermal properties of bio-based waste from Tetra Pak® panels and wool fibers (Hassanin *et al.*, 2018). Increased testing of waste product can lead to numerous benefits.

A simple test of insulating properties is to subject the material to a heat source and measure the temperature gradient as a function of time (Sparavigna, 2012). This method was developed for conducting materials. The R -value can be determined from

$$R = \frac{\Delta T}{\Phi_q} \quad (1)$$

$$\Delta T = R\Phi_q = -\kappa R|\vec{\nabla} T| \quad (2)$$

$$\kappa = \alpha\rho c_p \quad (3)$$

$$\Delta T = R\Phi_q = -\alpha\rho c_p R|\vec{\nabla} T| \quad (4)$$

$$\frac{1}{R} = -\frac{\alpha\rho c_p}{\Delta T}|\vec{\nabla} T| \quad (5)$$

$$\frac{1}{R} = -\frac{\alpha\rho c_p}{\Delta T} \sqrt{\left(\frac{\partial T}{\partial x}\right)^2 + \left(\frac{\partial T}{\partial y}\right)^2 + \left(\frac{\partial T}{\partial z}\right)^2} \quad (6)$$

The ΔT is the difference between the temperatures across the insulating barrier, α is the thermal diffusivity, ρc_p is the volumetric heat capacity and ∇T is the temperature gradient across the thermal barrier. The thermal diffusivity α can be measured experimentally using the heat equation

$$\frac{\partial T}{\partial t} = \alpha \nabla^2 T \quad (7)$$

$$\frac{\partial T}{\partial t} = \alpha \left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} \right) \quad (8)$$

which then reduces to

$$\frac{\partial T}{\partial t} = \alpha \frac{\partial^2 T}{\partial z^2} \quad (9)$$

for tall, narrow sample shapes where the x and y dimensions are small compared to the z dimension. This means that the R -value can also experimentally reduce to

$$\frac{1}{R} = \pm \frac{\alpha\rho c_p}{\Delta T} \left(\frac{\partial T}{\partial z} \right) \quad (10)$$

for the same reasons.

The theoretical temperature field provides a usable value for $\frac{\partial T}{\partial z}$ from Eq. (10). Based upon a solution to the heat equation of the form

$$T(z, t) = T_0 \sin(\omega z) e^{-\alpha\omega^2 t} \quad (11)$$

where T_0 is the initial temperature of the sample. Then the heat Eq. (9) becomes

$$\frac{\partial^2 T}{\partial z^2} = \frac{1}{\alpha} \frac{\partial T}{\partial t} = \frac{T_0}{\alpha} \sin(\omega z) (-\alpha\omega^2) e^{-\alpha\omega^2 t}$$

and

$$\begin{aligned}
 \frac{\partial T}{\partial z} &= \frac{1}{\alpha} \int \frac{\partial T}{\partial t} dz \\
 &= \frac{1}{\alpha} \int T_0 \sin(\omega z) (-\alpha \omega^2) e^{-\alpha \omega^2 t} dz \\
 &= -\omega^2 T_0 e^{-\alpha \omega^2 t} \int_0^L \sin(\omega z) dz \\
 &= \omega^2 T_0 e^{-\alpha \omega^2 t} \cos(\omega z) \Big|_0^L \\
 &= \omega^2 T_0 e^{-\alpha \omega^2 t} [\cos(\omega L) - 1]
 \end{aligned}$$

where L is the height in the z -dimension of the sample. The boundary conditions on the sample chamber ($\frac{\partial T}{\partial t} = 0$) provide values for ω .

$$\omega L = (2n + 1) \frac{\pi}{2} \quad (12)$$

Take $n = 0$ so that $\omega = \frac{\pi}{2L}$ and use the steady state limit so that

$$\frac{\partial T}{\partial z} = -\frac{\pi^2 T_0}{4L^2} \quad (13)$$

Finally,

$$\frac{1}{R} = \mp \alpha \frac{\pi^2}{4} \frac{\rho c_p}{L^2} \frac{T_0}{\Delta T} \quad (14)$$

Now, find ΔT from

$$\frac{\partial T}{\partial z} = \omega^2 T_0 e^{-\alpha \omega^2 t} \cos(\omega z)$$

where

$$\begin{aligned}
 T(z, t) &= \omega^2 T_0 e^{-\alpha \omega^2 t} \int \cos(\omega z) dz \\
 &= \omega^2 T_0 e^{-\alpha \omega^2 t} \sin(\omega z)
 \end{aligned}$$

In the steady state,

$$T(z, t) = \omega^2 T_0 \sin(\omega z)$$

Using the same values for ω as in Eq. (12) and evaluating $\Delta T = T(L, t) - T(0, t)$ gives

$$\Delta T = \omega^2 T_0 \sin(\omega z) \quad (15)$$

$$= \frac{\pi^2 T_0}{4 L^2} \quad (16)$$

Now, Eq. (14) becomes

$$\frac{1}{R} = \alpha \rho c_p \quad (17)$$

consistent with the definition of the R value for insulation.

Eq. (17) now provides a basis for the procedures used to establish the thermal properties of waste stream materials. They are:

- (1) Determine the thermal diffusivity (α) from experimental measurements of the sample temperatures as a function of time, according to Sparavigna (2012).
- (2) Compute the volumetric heat capacity (ρc_p) from experimental measurements of sample mass, volume, and an estimate of its specific heat capacity.
 - (a) The specific heat capacity (c_p) can be estimated at 1200 J Kg⁻¹ K⁻¹ from the values for wood and air (Table 1).
 - (b) The volumetric heat capacity (ρc_p) is then either

$$\rho c_p \approx \begin{cases} 31,200 \\ 58,800 \end{cases} \quad (18)$$

for 8 g and 15 g samples, respectively, in units of (J m⁻³ K⁻¹).

Table 1 Specific heat capacities (c_p) in common building materials

Substance	Phase	$c_p \left(\frac{\text{J}}{\text{kg}\cdot\text{K}} \right)$
Gypsum	Solid	1090
Asphalt	Solid	920
Pyrex	Solid	753
Soil	Solid	800
Wood	Solid	1200–2900
Air	Gas	1000

**Fig. 1** Schematic of apparatus used to characterize thermal properties of indirect materials. $L = 8$ cm is the same variable used starting with Eq. (12). $H = 12.5$ cm, $d = 7$ cm and $D = 10$ cm. The container portion of the apparatus had a mass of 164 g.

Methods

There are multiple methods for testing the thermal insulation properties of materials (Sparavigna, 2012; Sparavigna *et al.*, 1992). A straight-forward measurement is an apparatus consisting of thermocouples, voltmeters and an insulating sample chamber (Fig. 2). The samples for this article were donated by a large fibrous material manufacturer. Five different material types were used (deemed “a” through “e”). Each had a different ratio of typical fibrous material components: cotton, polyester, rayon, tencel, viscose, polyethylene terephthalate, *etc.* The specific composition and weave of the materials is proprietary (Fig. 1).

The thermal diffusivity of paper-like material samples can be measured experimentally to estimate the R -value of the material. The sample chamber in the apparatus is made up of two separated metal containers (Fig. 2). One thermocouple (TC 1) is placed at the top. Another thermocouple (TC 2) can be mounted at the entrance of the chamber, at the bottom in the figure. TC 2 measures the temperature near the heat source while TC 1 measures the temperature on the other side of the sample material.

The thermocouple sensors create measurable voltages proportional to the temperature at the site of the thermocouple. The sensing principle of the thermocouple relies upon what is sometimes called the Peltier-Seebeck effect and is schematically depicted in Fig. 2. Small temperature variations across a thermoelectric material result in a measurable voltage difference across the device. The voltages generated by the thermocouple sensors can then be recorded at regular time intervals to experimentally determine R -values of indirect wastestream materials.

The samples were parsed into bundles of either 15 g or 8 g loosely-packed, as-donated material. They were placed as evenly as possible into the sample chamber.

While heating the samples continuously, the thermocouple measurements were recorded at sixty second intervals. The samples were heated until the temperatures stabilized.

Results

All materials provided significantly better insulation than air alone. Thermocouple sensors read between 2.0 and 8.0 relative temperature units with just air in the sample chamber. All materials tested had relative temperature units much lower than that,

Fig. 2 A thermoelectric circuit composed of materials of different Seebeck coefficients (p-doped and n-doped semiconductors), configured as a thermoelectric generator. If the load resistor at the bottom is replaced with a voltmeter, the circuit then functions as a temperature-sensing thermocouple.

Fig. 3 Comparison of samples with temperatures measured at the chamber's top at TC 1. The other thermocouple, TC 2, consistently registered between 2.0 and 8.0 relative units. Five different material types (a–e) were tested in both 8 g and 15 g sample masses.

indicating they prevented the sample chamber temperature from rising to the air sample control temperature. The curves shown in the graphs indicate that the heat source would increase the temperature at the top of the sample chamber over time. After the heat source was removed, the temperatures began to drop again to room temperature (Fig. 3).

TC 2 results showed a consistent temperature of approximately the control sample temperature profile (heated room air). This remained between 2.0 and 8.0 relative units during measurements. The largest variation in insulating properties resulted from the amount of material tested. This indicates that more data would be helpful with larger amounts of material bundles. It raises the question, of whether the main benefit of the fibrous material is to block thermal convection and mixing. Another question is raised about the space-filling properties of the fibrous material and how that would impact the insulating properties.

Computation of the thermal diffusivity followed (Sparavigna, 2012). A minimization curve allowed determination of the value at approximately $4.5 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$. This is comparable with fibrous material. For reference, yellow pine wood has a diffusivity of $8.2 \times 10^{-8} \text{ m}^2 \text{ s}^{-1}$ and air a value of $1.9 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$ (Fig. 4).

Discussion

The data suggests that the amount of material used is extremely important and suggests that each material has a maximum performance density. Testing lateral heat flow (conductive) in addition to the upward (convective) heat flow tests would be

Fig. 4 Sample “a” heated for about an hour. A minimization curve ($I(\alpha)$) allowed determination of the value of the thermal diffusivity of $\approx 4.5 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$. For reference, yellow pine wood has a diffusivity of $8.2 \times 10^{-8} \text{ m}^2 \text{ s}^{-1}$ and air a value of $1.9 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$.

interesting. The sample materials should also be tested for flammability to give an indication of safety measures that would need to be considered in the event that the materials may become wall insulation.

The determination of the R value for one of the samples is a proof of concept; fibrous waste stream materials can be characterized according to their thermal insulative properties with relatively inexpensive equipment and in a reasonable amount of time. This method could be deployed “in the field” by automating the computation for faster analysis.

Conclusion

The “ R ” value for this waste stream material was determined to be $\approx 72 \text{ m}^2 \text{ K W}^{-1}$ or roughly R-10. This is typical for standard insulation materials such as silica aerogels and standard construction insulation panels. The experiment is an example of how research can lead to alternate uses of waste stream materials. The results show that waste stream materials have valuable properties that can be utilized in re-manufacturing.

Acknowledgments

The experimental data collection for this paper was done by Mr. Devon Manuele, an undergraduate majoring in Applied Science at the University of Wisconsin – Stout. Dr. Todd A. Zimmerman helped compute the minimization function values with a Python script. UW-Stout's Department of Chemistry and Physics provided the infrastructure and lab equipment. The samples were donated *via* UW-Stout's Discovery Center.

Introduction

Climate change and energy security concern increases the demand improving the internal combustion engine efficiency and emissions which may be met through the use of alternative fuels and clean combustion process. One of such alternatives is to use bio-hydrogen as an energy carrier and to extract energy using a modified internal combustion engines on account of its renewability, clean burning characteristics, high calorific value etc., (Verhelst and Wallner, 2009). It is also shown that compared to hydrocarbon fuels, hydrogen has very high flame speed and higher exergetic efficiency of combustion indicating greater effectiveness of transformation of the chemical exergy of the fuel into useful work (Rakopolous *et al.*, 2008). Due to its carbon free nature and high flame hydrogen combustion produces almost zero emissions of oxides of carbon and unburned hydrocarbon but produces considerably higher emissions of NO_x than gasoline fueled engine due to high adiabatic flame temperature (Ji and Wang, 2009). Many researchers have investigated the thermodynamic and emissions level performance of hydrogen fueled engines. Kahraman *et al.* (2007) carried out some investigations which show that thermal efficiency of the hydrogen engine was higher than that of a gasoline engine. Al-Baghdadi (2004) found that increased compression ratio is beneficial for enhancing the power output and thermal efficiency of the hydrogen engine. However, due to the engine operation in spark ignition mode NO_x emissions rose to higher level. Ganesh *et al.* (2008) claimed that thermal efficiency of the hydrogen engine was about 2% higher than that of the gasoline engine. A study conducted by Ji and Wang (2013) show that fuel energy flow rate was reduced with the increase of excess air ratio for the pure hydrogen fueled engine at idle and lean conditions.

These studies clearly show that use of pure hydrogen in SI engines only reduces the emissions of oxides of carbon and unburned hydrocarbons (UHC). The non-trivial exhaust gas emissions of nitrogen oxides and the particulate matter (PM) remain formed during combustion. Therefore in order to reduce the NO_x and PM along with the oxides of carbon and UHC, a modified combustion strategy is needed to utilize hydrogen in engines in a most eco-friendly manner. In this context, homogeneous charge compression ignition (HCCI) engine has been emerged due to its potential to reduce engine NO_x and

PM whilst still maintaining a higher thermal efficiency (Antunes *et al.*, 2008; Khaliq *et al.*, 2011). Therefore, pure hydrogen fueled internal combustion engine in HCCI mode is found to be one of the possible alternative for achieving zero – emission engine operation while maintaining higher efficiency and hence it could be a promising technology for sustainable surface transportation.

The purpose of the current study is to conduct a thermodynamic analysis of the pure hydrogen fueled internal combustion engine in HCCI mode using simultaneously the first and second law of thermodynamics. The latter through the concept of exergy, quantifies exergy losses and hence identifies the thermodynamic imperfections due to which a deviation is observed between the ideal and observed performance of engines. Results obtained through current research is a big source of data for the engine manufacturers to design an efficient and reduced emissions engine for transportation.

Engine Cycle Description

To facilitate the first and second law analyzes of a pure hydrogen fueled HCCI engine, its schematic diagram is shown in Fig. 1.

The ambient air enters the compressor which delivers air at high pressure and temperature followed by the heat exchanger which uses water as a cooling medium, reduces the compressed air temperature to the desired level (93°C). Next hydrogen which is stored at a high pressure of 200 bar in the cylinder is injected into the fuel vaporizer at a pressure of 6 bar and at an ambient temperature of 20°C. The pressure of hydrogen is reduced from 200 bar to 6 bar through a pressure reduction valve. The hydrogen at a pressure of 6 bar and temperature of 20°C mixes with the compressed air which enters fuel vaporizer at 93°C. The mixing process in the fuel vaporizer produced a homogeneous mixture of hydrogen and air, which then enters HCCI engine. An engine compression ratio of 17:1 is assumed to ensure auto-ignition of the hydrogen air charge where a chemical reaction in the freshly burned zone occurs under constant volume conditions, resulting in a pressure rise in the combustion products which are in a state of chemical equilibrium. The freshly burned products expand to equilibrate the cylinder pressure and hence develop power, and thereafter mix with the previously burned gases to form a homogeneous charge.

Fig. 1 Schematic diagram of a Bio-hydrogen-fueled HCCI engine.

Fig. 2 p-v representation of HCCI engine combustion.

The cylinder exhaust gases enter the turbine to generate power for the turbocharger. The power consumed by turbocharger compressor is more than the power developed by the turbine, therefore some power is extracted from the engine cylinder to meet out the power requirement of turbocharger.

The following assumptions are made for the proposed analysis of a pure hydrogen fueled HCCI engine (Antunes *et al.*, 2008).

- The HCCI combustion process is represented by a time dependent, variable volume well mixed reactor.
- The overall burn rates of HCCI combustion are typically fast and if correctly phased in the cycle could approximate ideal Otto cycle. Fig. 2 illustrates the PV diagram of an ideal HCCI operating condition.
- Fuel and air are premixed in the fuel vaporizer prior to entering the engine combustion chamber.
- The volumetric efficiency of the engine is 100% meaning the volume of air and fuel inducted into the engine cylinder is equal to the displacement of the cylinder.
- Thermal losses in ducts are negligible.
- Pressure drop in heat exchanger and duct is negligible.
- Turbocharger mechanical losses are neglected.
- Engine is assumed to operate at a constant speed of 2200 rpm and non-varying load.
- The residual gas fraction is considered as ($f = 0.03$), its value is not much effected at high compression ratio as assumed in the present analysis.

The engine details are given in Table 1.

Energy and Exergy Analyzes

For the transient operation of a HCCI engine configuration (engine cylinder, exhaust manifold, turbocharger etc.) experiencing mass exchange with the surroundings, the following equations holds for the energy and entropy balance of the component or system

$$\frac{dE_{cv}}{dt} = \dot{Q}_{cv} - \dot{W}_{cv} + \sum_i \dot{m}_i \left(h_i + \frac{V_i^2}{2} + gz_i \right) - \sum_e \dot{m}_e \left(h_e + \frac{V_e^2}{2} + gz_e \right) \quad (1)$$

The fundamental equation for combustion of hydrogen-air mixture in the HCCI engine may be written as

$$\frac{dS_{cv}}{dt} = \sum_i \frac{\dot{Q}_i}{T_i} + \sum_i \dot{m}_i s_i - \sum_e \dot{m}_e s_e + \dot{S}_{gen} \quad (2)$$

where, ϕ is greater-than-one number representing the ratio between the actual air flow rate and the theoretical flow rate.

Table 1 HCCI engine specifications

Displacement	1.9 L
Compression ratio	17:1
Bore	100 mm
Stroke	105 mm
Engine speed	2200 rpm
Ratio between actual and theoretical air (ϕ)	ϕ is greater than 1 number
Type of loading	Non varying load
Fuel	Hydrogen
Nature of combustion in HCCI engine	Bulk autoignition process controlled by chemical kinetics
Intake air cooling by water	Necessary to bring air at 93°C before fuel-air mixer
Mass flow rate of hydrogen	1.5×10^{-4} kg/s
Hydrogen injection pressure and temperature	6 bar and 20°C
Air inlet temperature	93°C
Cooling water inlet and exit temperatures	25°C and 35°C

Source: Khaliq, A., Trivedi, S.K., Dincer, I., 2011. Investigation of a wet ethanol operated HCCI engine based on first and second law analyses. Applied Thermal Engineering 31, 1621–1629. Antunes, J.M.G., Mikalsen, R., Roskilly, A.P., 2008. An investigation of hydrogen fuelled HCCI engine performance and operation. International Journal of Hydrogen Energy 33, 5823–5828.

Assuming, that, the system under consideration (fuel – air mixture) is an ideal gas, consisting of species that behave individually as ideal gases, the absolute entropy of the species ‘i’ at a given temperature and pressure (T, p) is given by Djermouni and Oudha (2014).

$$\bar{s}_i(T, p) = \bar{s}_i^0(p_o, T_o) + \int_{T_o}^T \frac{\bar{C}_{p_i}(T)}{T} dT - \bar{R} \ln \left(\frac{y_i p}{p_o} \right) \quad (4)$$

The superscript 0 and subscript 0 denotes the properties of species i, at ambient pressure and ambient temperature. The absolute entropy of a mixture at a given (T, P) is given by

$$\bar{s}_{mix}(T, p) = \sum_{i=1}^{i=n} y_i \bar{s}_i(T, p) \quad (5)$$

where, $\bar{s}_i(T_o, p_o)$ is the absolute entropy of a species i in kJ/kmol-K at an ambient pressure and temperature (restricted dead state), $\bar{C}_{p_i}$ is the specific heat of a species ‘i’ at a given temperature ‘T’ in kJ/kmol-K, $\bar{R}$ is the universal gas constant in kJ/kmol-K, y_i is the mole fraction of species i in the mixture and p is the absolute pressure of mixture and T is its temperature in K.

The specific heat of a particular species in the mixture $\bar{C}_{p_i}(T)$ at a given temperature is calculated by the relation

$$\frac{\bar{C}_{p_i}(T)}{\bar{R}} = \alpha + \beta T + \gamma T^2 + \delta T^3 + \epsilon T^4 \quad (6)$$

The values of constants, α , β , γ , δ and ϵ for a given species, are directly obtained from Rakopolous *et al.* (2008).

The absolute entropy of a mixture (fluid stream) at a given state is calculated after using Eqs. (3) and (4), and then the generation of entropy in any process of the engine cycle is evaluated after using Eq. (2).

The rate of lost available work $\dot{I}$ in a process is characterized by entropy generation $\dot{S}_{gen}$ in the process. For continuous process performed by a system, it can be written as

$$\dot{I} = T_o \dot{S}_{gen} \quad (7)$$

where $\dot{I}$ is the rate of lost available work during the process.

Performance Parameters

The overall performance of hydrogen fueled HCCI engine can be estimated based on first and second laws of thermodynamics.

Energy Efficiency (η)

The first law (energy) efficiency is the fuel utilization efficiency which is defined as ratio of specific brake thermal power output to the specific energy input and is given by

$$\eta_I = \frac{\dot{W}_{BT}}{\dot{m}_f LHV} \quad (8)$$

where LHV is its lower heating value of fuel in kJ/kg and WBT is the brake thermal power which may be evaluated as.....

$$\dot{W}_{BT} = 0.8W \cdot D.$$

where

$$\dot{W} \cdot D = \dot{m} \left[\frac{(p'_3 v'_3 - p'_4 v'_4)}{n-1} - \frac{(p'_2 v'_2 - p'_1 v'_1)}{n-1} \right]$$

Exergy Efficiency (η_{II})

The second law (exergy) efficiency is a more accurate measure of thermodynamic performance of the engine and is defined as the ratio of amount of exergy supplied in the product to the amount of exergy associated with the fuel. By definition, it is then given by the following expression (Nieminen and Dincer, 2010)

$$\eta_{II} = \frac{W_{BT}}{E_{fuel,in}} \quad (9)$$

where, $E_{fuel,in}$ is exergy of fuel in kJ/kg.

Results and Discussion

The effect of variation of excess air ratio and the effect of change in ambient temperature have been observed on the energy efficiency and exergy efficiency of the hydrogen fueled HCCI engine.

Effect of Excess Air

Fig. 3 shows the effect of variation of excess air in a fuel-air mixture on the energy and exergy efficiency of hydrogen fueled HCCI engine. It is observed that the energy efficiency based on first – law performance is initially increasing with the increase in excess air. This is due to the fact that lower value of excess air results in the increase of the temperature of air at the cylinder inlet which reduces the engine power output and hence results in a lower value of its energy efficiency. As the excess air increases temperature of the inlet air at the cylinder decreases which increases the engine power output and hence its efficiency. It is observed that further increase in excess air results in the decrease of energy efficiency. This is due to the reason higher excess air, increases its much lean burn operation characteristics which results in lowering the combustion temperature or mean temperature of heat addition and hence results in lowering the energy efficiency of the engine. It is found that between the excess air of 20% and 40% respectively, the energy efficiency ranged from 42% to 40% and a maximum efficiency of 45% is observed at the excess air of 25%. The higher value of energy efficiency even for lean operation of engine is obtained due to its high compression ratio (17:1) which is permitted in HCCI mode not in SI mode.

Fig. 3 Effect of variation of percent excess air on hydrogen operated HCCI engine efficiencies.

The variation of exergy efficiency of the HCCI engine with the increase in excess air is also shown in Fig. 3. A significant reduction in exergy efficiency is observed at the lower values of excess air and it becomes gradual at higher values of excess air. This is due to the reason that chemical exergy losses are high at lower values of excess air due to the presence of combustible product species, which results in the significant reduction of the exergy efficiency of the engine. As the excess air in the fuel-air mixture increases the combustion temperature decreases which results in the higher combustion irreversibility and lower exergy loss due to heat transfer between the combustion zone and the cylinder wall. The increase in exergy destruction during combustion dominates over the reduction of exergy loss via heat transfer. Therefore, a gradual reduction in the exergy efficiency is observed at a higher percent of excess air. A wide range of exergy efficiency of 25%–45% is obtained between the excess air of 20% and 40%, respectively.

Effect of Ambient Temperature

There have been prior attempts for evaluating the effect of ambient temperature on the energy and exergy efficiency of an alternate fueled HCCI engine. A recent analytical investigation by Khaliq *et al.* (2011) on wet ethanol fueled HCCI engine is a significant effort in this area.

In the present study, the effect of ambient temperature on energy and exergy efficiency of hydrogen fueled HCCI engine is shown in Fig. 4. It is found that energy efficiency decreases with the increase in ambient temperature while the exergy efficiency increases with the same. The reason for this kind of trends obtained may be noted as; increase in ambient temperature increases the fuel-air mixture intake temperature which results in reduced power output due to a reduction in volumetric efficiency and hence the lower energy efficiency of the engine. Another reason for this kind of trend is, hydrogen has high energy content in the reactant system (represented by the product of the fuel moles and the heating value) and consequently loses more heat from combustion zone to cylinder wall which further reduces the energy efficiency. Therefore, the decrease in energy efficiency with the increase in ambient temperature is the combined effect of increase in fuel-air intake temperature and type of fuel (hydrogen) used for the analysis.

The reason for increase in exergy efficiency with the increase in ambient temperature may be highlighted as; first increase in ambient temperature results in a decrease of excess air ratio in a fuel-air mixture which results in the higher combustion temperature and hence the lower combustion irreversibility. Second, the fuel used hydrogen has the simplest (lighter) molecular structure which results in a lower entropy generation during combustion due to the formation of chemically complicated molecule from the less chemically structured molecule. Therefore, an increase in exergy efficiency of hydrogen fueled HCCI engine with the increase in ambient temperature shown in Fig. 4 is the combined effect of above two discussed reasons. The exergy efficiency in the range of 32%–36% is obtained between the ambient temperature of 13°C and 41°C respectively while the energy efficiency is obtained in the range of 48%–44% between the same range of ambient temperatures.

Fig. 5 shows the percentage of fuel (hydrogen) exergy destroyed during various processes of the HCCI engine at mean operating conditions ($T_o = 300\text{K}$ and excess air = 30%). A study based on comprehensive second law analysis reveals that the majority of exergy is destroyed in HCCI engine (compression, combustion, expansion) which is around 37.83% of the fuel exergy supplied, rest of the fuel exergy destruction occurs in turbocharger, heat exchanger and turbine; which are of the values of 5.43%, 4.36%, and 4.14% respectively. A 40.34% of fuel exergy is obtained as the work output of the engine, and around 7.83% of fuel exergy is lost via engine exhaust. The distribution of 100% fuel (hydrogen) exergy supplied to the combustion engine in HCCI mode may be represented as, around 52% of fuel exergy is destroyed due to irreversible processes in various components of the HCCI engine 40.34% is produced as work output, and 7.83% is lost via exhaust.

The results obtained in the analysis for hydrogen fueled HCCI engine especially the variation of energy and exergy efficiency in Fig. 4, have been compared with the results obtained for another promising renewable fuel (wet-ethanol) driven HCCI engine under same operating conditions (Khaliq *et al.*, 2011) in order to clarify the theoretical efficiency benefits obtained in the current study. These comparative results are graphed in Fig. 6. Comparison of the results clearly shows that hydrogen fueled HCCI engine

Fig. 4 Effect of variation of ambient temperature on Hydrogen operated HCCI engine efficiencies.

Fig. 5 Percentage of exergy destruction in each component of hydrogen operated HCCI engine.

Fig. 6 Comparison of ambient temperature effect results of hydrogen and wet-ethanol for energy and exergy efficiency of HCCI engine.

provides a higher energy and exergy efficiency than wet-ethanol fueled HCCI engine for the same operating conditions. The energy efficiency for both the fuels shows the same trend of decreasing with the increase in ambient temperature but the exergy efficiency in case of hydrogen increases with the increase in ambient temperature and decreases in case of wet-ethanol with the same. This opposite trend for variation of exergy efficiency between the two fuels is observed due to the fact that hydrogen has much simpler molecular structure than wet-ethanol. Combustion of hydrogen results in less entropy generation than ethanol during combustion and hence provides a higher exergy efficiency of the engine.

Conclusions

The thermodynamic analysis clearly reveals the parts of the operating cycle where the capability of the working medium to do useful mechanical work is destroyed due to thermodynamic irreversibilities (such as combustion) and losses through undesirable exergy transfers (such as heat transfers to the cylinder walls and loss of thermal exergy to the exhaust). The results obtained based on first and second law analyzes may be summarized as follows:

- (1) A maximum energy efficiency of 45% and an exergy efficiency of 37% were obtained at an excess air of 25% and an ambient temperature of 300K.
- (2) Exergy analysis reveals that maximum exergy destroyed in HCCI engine which is 37.83%. Exergy destruction in the turbo-charger, heat exchanger, and turbine are of the values of 5.43%, 4.36%, and 4.14% respectively. Exergy destruction in fuel-air mixer was found to be negligible.
- (3) Around 52% of the fuel (hydrogen) exergy is destroyed in various components of HCCI engine due to their irreversible operation, 40.34% is produced as available work output, and 7.83% is lost via engine exhaust.

The results, obtained in the present study is a source of data for researchers and engineers to obtain a better design of hydrogen fueled HCCI engine for nearly zero emission operation.

Advanced Vehicle Systems and Technologies: Economic and Environmental Implications

Trina Dutta, JIS College of Engineering, Kalyani, India

Introduction

As per current scenario, the steadily growing transportation sector is responsible for nearly 60% of total world oil demand. It is believed that in between 2006 and 2030, the oil demand from transportation will reach around three quarters of the projected increase in oil demand ([U.S. Energy Information Administration, 2010](#); [An, 2010](#)).

Not only the energy crisis, environment is a big concern. The conventional internal combustion Engine Vehicles (ICEVs) run by fossil fuels (i.e., gasoline or diesel) emits the major greenhouse gases (GHG) like Carbon-di-Oxide (CO₂), Methane (CH₄) and Nitrous Oxides (N₂O). Besides, Hydro-Fluorocarbon (HFCs) leaked out from air conditioning also contribute to GHG emissions. Not only that, transportation sector also emits harmful criteria pollutants like Carbon Monoxide (CO), Ozone (O₃), and Aerosol ([Atabani et al., 2011](#)).

To improve the fuel economy and reduce carbon dioxide emission in the transportation sector different types of initiatives can be opted like; (i) Fuel economy and greenhouse gas emission standards, (ii) Consumer information and labeling, (iii) Research and innovation for vehicle technology, (iv) De-emphasize increases in vehicle acceleration and horsepower performance, (v) Use of alternative fuels such as advanced bio-fuels, hydrogen fuel cells and natural gas as alternatives to oil and alternative power plants such as hybrid vehicles (HEV) and fuel cell vehicles (FCV), (vi) Vehicle taxation and charges linked to emissions performance, (vii) Eco-driving, (viii) Reducing the distances travelled per vehicle, (ix) Consumer behavior and congestion avoidance, (x) Investing in rail for freight and also passengers, (xi) Establishing green zones and green parking places for clean and fuel efficient cars such as in big cities, (xii) Offering incentives for low emission vehicles to encourage investment in appropriate emission reduction technologies ([Wagner et al., 2009](#); [Sierra club, 2010](#); [Cheah and Heywood, 2011](#); [Van West, 2006](#); [Pundir, 2010a,b](#); [IEA, 2010](#)).

Key Fuel Economy Reports

Considering huge potential of energy saving, fuel economy standards, labeling of vehicles and technologies advancement have been promoted in the transportation sector.

Fuel Economy and Greenhouse Gas Emission Standards

Fuel economy and greenhouse gas emission standards have proven to be one of the most effective tools in controlling oil demand and greenhouse gas (GHG) emissions. Globally, major regions around the world have implemented or proposed various fuel economy and greenhouse gas (GHG) emission standards. Among them Japan and European Union (EU) led the world with the most stringent passenger vehicle fuel economy standards. The Environmental Protection Agency (EPA) enacted the Clean Air Act (CAA) and National Highway Traffic Safety Administration (NHTSA) implemented the Energy Policy and Conservation Act to maintain tailpipe carbon emission and fuel economy for both passenger cars and light-duty trucks ([Atabani et al., 2011](#)).

Labeling

Labeling of vehicles plays an important role in consumers' vehicle purchasing decisions between similar vehicles that have different fuel efficiency ratings. Labeling provides the information regarding passenger car model, year of application of the label, absolute fuel consumption [l/100 km, km/l], CO₂ emission, comparison of relative fuel economy [%], fuel costs for 50,000 km. Labeling accompanied by standards of an appropriate type and level of stringency may yield synergistic results and different regions like USA, United Kingdom, Canada, China and Australia already reviewed several fuel economy levels ([Atabani et al., 2011](#)).

The Technological Advancement

The technological advancement plays an important role to improve fuel efficiency of motor vehicles. Throughout the history of automobiles the technology and design improvements have been always directed towards improvement of engine, transmission, vehicle body and accessories for obtaining higher fuel economy.

Case studies

The first generation Toyota Prius introduced in 1998 with 1.5 l, 43 kW gasoline engines and upgraded to 53 kW in 2001. The second generation Toyota Prius produced in 2004, adjudged as best engineered vehicle of the year by the Automotive Engineering

International. It uses a 4-cylinder gasoline engine with DOHC, 4-valve/cylinder and VVTi. The 2001 model gave 48 mpg (20.4 km/l) on CAFÉ (Corporate Average Fuel Economy Program) test cycle. The second generation Toyota Prius weighs 1250 kg and gives 55 mpg (23.4 km/l) on combined US city and highway fuel economy test cycle compared to the CAFE standard of 27.5 mpg.

A number of manufacturers like Toyota, Honda, Ford and Mercedes have introduced hybrid SUVs. These SUVs are for the customers who normally preferred high power SUVs using V-6 and V-8 engines. A 2004, hybrid SUV using gasoline engine gave 27.6 mpg and a diesel engine powered hybrid SUV gave 33 mpg on CAFE test cycle (*Automotive Engineering International, 2004*). Chevrolet Tahoe, GM hybrid SUV with 8 passenger capacity, 2810 kg curb weight achieves 50% better city cycle and 30% better combined cycle fuel economy compared to its gasoline engine counterpart (*Automotive Engineering International, 2008*).

Advancement of Vehicle System and Technology

Vehicles are broadly classified into Internal Combustion Engines (ICEVs) and Electric Vehicles (EVs). Based on hybridization ratio with ICEVs, EVs are commonly categorized into hybrid electric vehicles (HEVs), plug-in hybrid electric vehicles (PHEVs) and battery electric vehicles (BEVs).

Internal Combustion Engine Vehicle (ICEV)

ICEV is a heat engine where fuels ignited with an oxidizer (usually air) in a combustion chamber. Then the chemical energy is transformed to heat energy and kinetic energy to propel a vehicle.

Conventional ICEV is mostly dependent on petroleum based fossil like gasoline, diesel oil, liquefied petroleum gas (LPG) and compressed natural gas (CNG) (*Balat and Balat, 2009*). It has no Electric Motor (EM) to support the fuel economy.

Micro-hybrid electric vehicles (micro-HEV) take the assistance of EM to restart the ICEV from off state without contributing any power to propel the vehicle. Currently, the Citroën C3 is being sold in Europe, is a micro-HEV (*Tie and Tan, 2013*).

Electric Vehicle (EV)

Robert Anderson first invented Electric-powered vehicle in between 1832 and 1839 powered by non-rechargeable primary cells (*Guarnieri, 2011*). The technology advancement of DC electric motor and rechargeable battery introduced EV commercially into the market first time in 1897. In just three years, EVs took up 28% of the road vehicles and was the favored vehicle of choice (*International Energy Agency Internet, 2014*). In 20th century, after invention of gasoline powered vehicles such as Ford Model T, Electric Vehicle faded out of popularity due to availability of cheap petrol and distance travelling limitation of EVs. But recently the global warming issue and depletion of fossil fuel brought the EV back and it was reborn due to rapid development of power electronics. Governments had implemented regulatory actions to reduce air emissions and promote electric and hybrid vehicles development. Toyota introduced the world's first commercial hybrid electric vehicle (HEV), Prius in Japan and 18,000 units were sold in the first production year (*Bellis, 2014*). As the oil price kept increasing, more automakers were committed to vehicle electrification. From year 2010 onwards, battery electric vehicles (BEVs) and plug-in hybrid electric vehicles (PHEVs), such as Nissan Leaf, Mitsubishi i-MiEV, Chevrolet Volt and Tesla Model S have started to enter into automotive industry (*Yong et al., 2015*).

Battery Electric Vehicles (BEVs) operate purely on the battery power, whereas the hybrid Electric Vehicles HEVs and PHEVs usually propel through a combination of two energy sources: internal combustion engine and electric motor. HEVs cannot accept charge from external energy sources, such as power grid. The battery is charged by the built-in internal combustion engine or through an energy recovery mechanism called regenerative braking which converts the kinetic energy into chemical energy and stores in battery for later use. PHEVs are similar to HEVs but with extra features, such as larger battery packs and can be recharged from the distribution grid.

A few power train configurations are developed for HEVs and PHEVs in order to achieve different objectives, such as improve fuel economy, increase power and minimize cost. The most common power train configurations of HEVs and PHEVs are series, parallel and series-parallel configuration, as depicted in *Fig. 1* (*Yong et al., 2015*).

As shown in *Fig. 1(a)*, a series HEV or an extended range electric vehicle uses power from electric motor as the only propulsion source. Other than recharging the battery by regenerative braking, an internal combustion engine and a generator are included to recharge the battery whenever the state of charge (SOC) of the battery is low. The electric motor is mechanically attached to the transmission and wheels. Meanwhile, the internal combustion engine is mechanically decoupled from the transmission and not connected to the wheels. The series HEV is suitable for city driving as it can deal with frequent stop-and-run driving pattern. This type of HEV can improve the overall vehicle efficiency to around 25% and is simpler to design, control and implement (*Tie and Tan, 2013*).

A HEV with typical parallel power train configuration is depicted in *Fig. 1(b)*. In a parallel HEV, both the electric motor and internal combustion engine are mechanically coupled to transmission and simultaneously transmit power to turn the wheels for vehicle propulsion. Due to two propulsion sources in a parallel HEV, the overall vehicle efficiency improvement of this HEV type is more than series HEV, approximately 40% more efficient than conventional car (*Tie and Tan, 2013*). A parallel HEV is suitable for city driving pattern and also highway driving pattern because electric motor and internal combustion engine can complement each other during different driving conditions. Some available parallel HEVs in market now are Honda Insight and Ford Escape.

Fig. 1 Power train configurations: (a) Series HEV, (b) Parallel HEV, (c) Series-parallel HEV, (d) Series PHEV, (e) Parallel PHEV, (f) Series-parallel PHEV. Reproduced from Yong, J.Y., Ramachandaramurthy, V.K., Tan, K.M., Mithulananthan, N., 2015. A review on the state-of-the-art technologies of electric vehicle, its impacts and prospects. *Renew. Sustain. Energy Rev.* 49, 365–385. Available at: www.elsevier.com/locate/rser.

The series-parallel HEV, as shown in **Fig. 1(c)**, combines the features of series HEV and parallel HEV. Both the electric motor and internal combustion engine are mechanically coupled to transmission and wheels. The series-parallel HEV can run in either series or parallel mode. Despite having the benefits of both series HEV and parallel HEV, the design of a series-parallel HEV is much more complicated and costly. Toyota Prius is an example of a commercial series-parallel HEV.

Similar to HEV, PHEV can have series, parallel and series-parallel power train configuration with additional on-board battery charger, as depicted in **Fig. 1(d–f)**. However, PHEV can be plugged-in to power grid and externally charged. PHEV has larger battery pack and can propel in all-electric drive mode for longer period compared to HEV. There are two operating modes for PHEV, which are charge depleting mode and charge-sustaining mode (Emadi, 2011). PHEV usually operates in charge-depleting mode at vehicle start up, where the vehicle propulsion power comes from battery power. When the battery state of charge reaches a predefined threshold, charge-depleting mode is switched to charge-sustaining mode, where the internal combustion engine turns on. Hence, vehicle is powered by two sources and the battery state of charge is maintained at the predefined threshold in charge-sustaining mode.

Fig. 2 shows a typical power train configuration of BEV. BEV uses electric motor as the sole propulsion source. Therefore, BEV has all electric propulsion system and always operates in charge-depleting mode. The large battery packs can be recharged through

Fig. 2 Typical power train configuration of BEV. Reproduced from Yong, J.Y., Ramachandaramurthy, V.K., Tan, K.M., Mithulananthan, N., 2015. A review on the state-of-the-art technologies of electric vehicle, its impacts and prospects. *Renew. Sustain. Energy Rev.* 49, 365–385. Available at: www.elsevier.com/locate/rser.

regenerative braking on drive and externally charged when the vehicle stops. Since BEV has all-electric propulsion system, the distance it can travel is based on the battery capacity. For instance, Nissan Leaf has a 24 kWh lithium-ion battery packs installed and can travel up to 160 km in a single full charge. Generally, BEV is suitable for city drive as it has limited all-electric drive range. However, BEV has decent benefits, such as zero tailpipe emissions and better vehicle performance (Yong *et al.*, 2015).

Battery

Battery is major storage device which consists of one or more electrochemical cells that can convert the stored chemical energy into electrical energy. It has been a major focus of research since batteries cost as much as one-third of the total EV cost.

The Lead-acid battery is most commonly used being the cheapest one. But it was replaced soon by Nickel based battery as there were few apparent drawbacks of Lead-acid battery, like low energy density, heavy; require inspection of electrolyte level and is not environment friendly. Afterwards lots of developments were done in battery technology with nickel–cadmium (Ni–Cd), nickel–metal hydride (Ni–MH), ZEBRA battery or Sodium-nickel chloride (Na–NiCl₂).

Introduction of the Lithium based battery shifted EV into a new era and dominated the most recent groups of EVs. Such Lithium-ion battery packs are used in Nissan Leaf, Mitsubishi i-MiEV, Tesla Models and Chevrolet Volt, which are the top EV choices at the present time.

But none of the battery technologies is free from drawbacks. So developments are still ongoing with different promising technologies like lithium–sulfur (Li–S), zinc-air (Zn-air) and lithium-air (Li-air). The theoretical high energy density of more than 1700 Wh/kg allows Li-air battery to compete with conventional ICEVs (Rahman *et al.*, 2014). But the Li-air battery is still in the prototype stage and has not been commercialized yet.

Table 1 shows the comparison of available battery technologies for EV application. The characteristics of the batteries, such as nominal voltage, energy density, and specific power, and lifecycle, percentage of self discharge per month, memory effect, operating temperature and production cost per kWh have been numerically revealed in details.

Economic Aspect

At a first glance, the economic impact of EV deployment is not positive. Although EV has low operating cost due to the use of efficient electric motor and inexpensive electricity (Windecker and Ruder, 2013), but has higher initial purchase cost for the expensive battery component. Many actions have been implemented to ease the high initial purchase cost of EV, such as mass-producing EVs (Gass *et al.*, 2014), implement energy trading policy (Lunz *et al.*, 2012) and adopt appropriate charging strategies (Karabasoglu and Michalek, 2013). One hand the EV requires high initial purchase cost than ICEV and on the other hand the power grid must have more generation capacity for the additional EV load demand.

The power demand can be optimized by implementation of the smart grid. The smart grid is a modernized electrical power grid that utilizes the computer-based remote control and automation to improve the reliability, efficiency and sustainability of the power supply (Bhatt *et al.*, 2014). As it is the two-way communication between utility and customer, customers can help to balance the energy supply and demand by changing their electricity uses pattern (Smart Grid Information Clearing house Internet, 2014). Additionally, due to intelligent monitoring control, the self healing smart grid takes immediate corrective measures to restore itself from disruption, and provides better reliability and reduces risk against attacks and natural disaster (Reddy *et al.*, 2014).

The proper management of Vehicle-to-grid (V2G) technology in smart grid brings active power regulation. Unidirectional V2G technology is inexpensive and does not degrade the EV battery from discharging since it only controls energy flow from the power grid to EV (Sortomme and El-Sharkawi, 2011). The main driver for unidirectional V2G deployment is introduction of an energy scheduling or incentive system for the EV owners for charging their EVs during off-peak periods (Fasugba and Krein, 2011; O'Connell *et al.*, 2012). The controlled EV charging will disperse the EV loads over the off-peak periods and level the load profile for cost saving and power losses reduction (Sortomme and El-Sharkawi, 2012, 2011) and mutual benefits for EV owners and power grid attained.

Table 1 Comparison of EV battery types

Battery type	Normal voltage (V)	Energy density (Wh/kg)	Volumetric energy density (Wh/L)	Specific power (W/kg)	Life cycle	Self discharge (% per month)	Memory effect	Operating temperature (°C)	Production cost (\$/kWh)
Lead acid (Pb-acid)	2.0	35	100	180	1000	<5	No	− 15 to +50	60
Nickel-cadmium (Ni-Cd)	1.2	50–80	300	200	2000	10	Yes	− 20 to +50	250–300
Nickel-metal hydride (Ni-MH)	1.2	70–95	180–220	200–300	> 3000	20	Rarely	− 20 to +60	200–250
ZEBRA	2.6	90–120	160	155	> 1200	<5	No	+ 245 to + 350	230–345
Lithium-ion (Li-ion)	3.6	118–250	200–400	200–430	2000	<5	No	− 20 to +60	150
Lithium-ion polymer (LiPo)	3.7	130–225	200–250	260–450	> 1200	<5	No	− 20 to +60	150
Lithium-iron phosphate (LiFePO ₄)	3.2	120	220	2000–4500	> 2000	<5	No	− 45 to +70	350
Zinc-air (Zn-air)	1.65	460	1400	80–140	200	<5	No	− 10 to +55	90–120
Lithium-sulfur (Li-S)	2.5	350–650	350	–	300	8–15	No	− 60 to +60	100–150
Lithium-air (Li-air)	2.9	1300–2000	1520–2000	–	100	<5	No	− 10 to +70	–

Available from: <http://www.research.com/johnsonliarbaty/Session4-350-Johnson.pdf>. Christensen, J., Albertus, P., Sanchez-Carrera, R.S., et al., 2012. A critical review of Li/air batteries. *J. Electrochem. Soc.* 159 (2), 1–30.

Implementation of bi-directional V2G technology can bring different benefits to EV deployment like peak saving, load leveling and voltage regulation. Based on scale of EV fleet V2G technologies categorized as vehicle-to-home (V2H), vehicle-to-vehicle (V2V) and Vehicle-to-grid (V2G) (Berthold *et al.*, 2011; Liu *et al.*, 2013; Ghosh *et al.*, 2013).

V2H is used within home automation network and hence it has the smallest scope among all the categories. In a home automation network, the excessive power generation from the home solar photovoltaic unit can be stored by the EV. This power can be discharged towards the other smart appliances in case of low renewable generation. V2H technology in combination to the renewable distributed generation is able to create a safe, energy efficient and eco-friendly living environment (Berthold *et al.*, 2011). Wherever there is a larger EV fleet context like EV parking lots present at commercial buildings, they are significant and the energy exchange of all EVs can contribute towards certain objectives. V2V technology allows energy sharing among EVs (Liu *et al.*, 2013). The V2G technology can be used effectively to transfer energy from the power grid to charge the EVs. It can also be used to discharge the EVs batteries into power grid for grid support (Ghosh *et al.*, 2013; Yilmaz and Krein, 2012).

But utilizing EV battery in the V2G technology increases the EV charging and discharging cycles, which accelerates the battery degradation. So, more research is yet to be conducted to improve the technical and economical performances of EV battery.

Environmental Implications

Life Cycle Assessment (LCA)

LCA is a systematic tool for environmental impact related to any goods and services. The total life cycle stages start from material acquisition and manufacturing to use and end-of-life sometimes referred to as “cradle-to-grave” (Baptista *et al.*, 2011; Messagie *et al.*, 2010; Van Mierlo *et al.*, 2003) or as “vehicle cycle” (Gao and Winfield, 2012; Jaramillo *et al.*, 2009; Lane, 2006). In the ISO standard, the terminology is used as “equipment life cycle” (ISO, 2006).

The wells-to-wheel (WTW) study is one type of LCA of vehicles, which focuses on the life cycle of the energy carrier used to propel the vehicle, such as liquid fuel or electricity (Fig. 3). The WTW life cycle can be subdivided into the well-to-tank (WTT) stage, which focuses on the delivery of energy from its source to the storage equipment in the vehicle, and the tank-to-wheel (TTW) stage, where the energy carrier is used to propel the vehicle during operation. The WTT stage involves all processes from harnessing a primary energy flow or stock to different forms of conversion, distribution, and storage of energy carriers. The environmental impact of the WTT stage differs a lot, depending on how the energy carrier is produced. For example, there is a large difference between electricity produced from hydro-power and coal-fired plants.

The present transportation sector is mostly dependent on gasoline or petrol for propulsion and there was no interconnection between the transportation and power grid before Electric Vehicles came into the market.

EV was widely adopted in the market as it can be plugged-into power grid to receive energy. Although EVs have zero tailpipe emission, but the EVs use energy from power grid to charge their batteries and the carbon intensive power generation process is mostly dependent on fossil fuels and emits greenhouse gases as well.

Fig. 3 Simplified view of the Well-to-wheel and equipments flows (a more detailed view include, for example, recycle option). Reproduced from Nordelöf, A., Messagie, M., Tillman, A.M., Söderman, M.L., Van Mierlo, J., 2014. Environmental impacts of hybrid, plug-in hybrid, and battery electric vehicles – What can we learn from life cycle assessment? *Int. J. Life Cycle Assess.* 19, 1866–1890.

So the point of arguments is that the electric powertrains are more energy efficient for propelling vehicles than conventional internal combustion engines fuelled by petrol or diesel or not. The full electric propulsion does not emit tailpipe emissions (IAE, 2011; Sadek, 2012). In addition, electric powertrains can assist in decoupling the transport sector from its heavy reliance on fossil fuels. On the other hand, electric vehicles may require additional electricity production (Tran et al., 2012) and this can be done using several different energy sources with diverse environmental impacts. Furthermore, electric powertrains require new advanced components (Chan, 2007), causing additional, or at least different, environmental impacts compared to conventional vehicles.

To solve the argument LCA studies come in many shapes and cause diverging arguments about environmental implication. WTW approach used to guide government promotion policies toward different types of powertrains and alternative fuel options (Ou et al., 2010).

In the most thorough review of LCA of electric vehicles, Hawkins et al. (2012) benchmarked 55 studies and also surveyed their own recommended practice and definition of a state-of-the-art complete LCA of electrified vehicles. It was argued that such studies have limited utility for informing policy makers as they only cover limited subsets of the complete system (Hawkins et al., 2012).

Helmerts and Marx (2012) compiled a broad description of technical characteristics and environmental impacts of electric and hybrid vehicles and concluded that electric vehicles have many benefits over conventional ones, but that the LCA literature on the subject “is complex.”

Nanaki and Koroneos (2013), Windecker and Ruder (2013) and Lorf et al. (2013) concluded that EVs have the lowest wells-to wheels emission.

But few cases have shown the reverse result. For instance, the Texas power grid, which has a mix of coal-and natural gas-fired generation, has been shown to yield higher emissions from EVs than ICEVs (Sioshansi et al., 2011). Similarly, the Ohio power grid with coal-fired generation yields higher SO_2 and NO_x emissions with use of EVs, although a CO_2 emissions reduced upto 24% from EVs than ICEVs (Weiller, 2011). These results conclude that EVs could not be environmental-friendly if EVs are charged from a dirty powergrid.

Althaus (2012) observes that results come out as diverging and that there is “a rather weak consensus” on the environmental performance of electric vehicles. Also, Frischknecht and Flury (2011) argue that results are diverging and, as an example, mention that emissions for electric vehicles vary between 95 and 240 g $\text{CO}_2\text{-eq./km}$.

Environmental Impact Assessment

For the environmental impact assessment a LCA needs to be extensive, complete and must cover impacts on three important areas of protection: natural environment, natural resources, and human health (ISO, 2006).

Natural environment

The airborne pollutants are mainly caused by combustion in the vehicle or at a power plant. The typical impact of airborne pollutants includes global warming potential (GWP), reporting all GHGs as CO₂-equivalents; photo-oxidant creation potential (POCP), which indicates how local air pollutants (NO_x and unburned hydrocarbons) build up smog under the influence of sunlight and harm both health and growing crops; Eutrophication potential (EP) which covers the effect of macronutrients in soil and water (including NO_x). Additionally, the acidification potential (AP) indicates the potential environmental impact of acidifying substances such as NO_x and sulfur oxides (SO_x) (Nordelöf *et al.*, 2014).

Natural resources

Abiotic resource depletion potential (ADP) aggregates the abiotic resource uses of metals and oil and often expressed in terms of antimony equivalents (kg Sb-eq.). Notter *et al.* (2010) compared ADP for two different versions of a vehicle in the compact class: an ICEV and a BEV and the results obtained from the study were around 260 kg Sb-eq./vehicle life (26% equipment cycle and 74% WTW cycle) for the ICEV and 190 kg Sb-eq./vehicle life (41% equipment cycle and 59% WTW cycle) for the BEV.

In previous ADP characterization the fossil energy depletion used to get more weightage, but recently, the frequently used Life Cycle Impact Assessment (LCIA) indicators, for example ReCiPe2008, placing more weightage on copper and nickel (Goedkoop *et al.*, 2012). Also, materials which currently play a key role in vehicle electrification, such as lithium and rare earth metals, are not covered by any of the easily available LCIA methods (Goedkoop *et al.*, 2012; Goedkoop and Spriensma, 2001; Joliet *et al.*, 2003).

Human toxicity potential (HTP)

Toxic emission at manufacturing stage specially connected with battery production of Electric vehicle was highlighted by Hawkins *et al.* (2013). The Human toxicity potential (HTP) analyzed in units of 1, 4-dichlorobenzene(DCB) equivalents, a well-known pesticide (Messagie, 2013).

Not only manufacturing, mining processes also have significant role in HTP as excavation is required for metal production as well as nuclear and fossil electricity. Material processing is especially energy intensive, and leakage from the waste disposal of mining spoils of nuclear and hard coal energy contributes to toxicity (Dones *et al.*, 2007). High use of copper and nickel, in batteries and electric motors, and copper and gold, in power electronics, increase disposal of mine tailings containing sulfides (Classen *et al.*, 2009). Consequently, improved waste handling in the mining industry and a less coal dependent energy mix could dramatically change these results and decrease the environmental load of BEVs.

But human toxicity and various types of ecological toxicity are complicated and uncertain as it relates different substances, their inherent toxicity, persistency and accumulation in the food chain (Finnveden *et al.*, 2009). The human health damage is caused not only by human toxicity, but also contributed by global warming, particulate matter formation, photochemical oxidant formation, ozone depletion, and ionizing radiation. As for example ReCiPe2008, climate change as a consequence of global warming contributes most to human health damage caused by vehicles (Goedkoop *et al.*, 2012). Calculated by this way, the petrol and diesel vehicles thus have a larger impact on human health than the BEV (Nordelöf *et al.*, 2014).

Key Remedies

Recycling

Recycling is a key factor for the environmental impact and battery is the main focus to recover the virgin material. The potential for recycling of lithium-ion batteries, which is both energy efficient and has high recovery rate, has been investigated in several papers (Dunn *et al.*, 2012; Gaines *et al.*, 2011; Li *et al.*, 2013; Sullivan *et al.*, 2011). However, highly efficient recycling processes are currently in practice only in the case of lead acid batteries.

This means that for newer technologies, an entirely new and large-scale recycling industry must be put in place if these results are to be realized (National Research Council, 2013). Additionally, battery technology is progressing very rapidly and data for environmental performance outdates quickly. Today it is often argued that the battery will last as long as the vehicle (Zackrisson *et al.*, 2010).

Interaction of renewable energy sources (RES) with V2G in smart grid

Initiatives have been taken to make the power grid greener with the wide employment of green renewable energy sources (RES) to reduce the wells-to-wheels emissions of EVs.

The adoption of Renewable energy sources primarily solar photovoltaic and wind energy, into power grid can create a greener and more sustainable electric power system. But these energy sources are not continuous and dependent on weather condition. The power generation fluctuates due to the variation of wind speed and solar irradiance. This intermittency issue of RES is the main barrier for the RES deployment. This issue can be resolved by using stationary energy storage system which can absorb excessive RES generation and supply in case of low RES generation (Mwasilu *et al.*, 2014). But it requires high investment. The issue has been

resolved by integration of bi-directional Vehicle-to-grid (V2G) technology and RES in smart grid system. EV charging can be utilized to stabilize the inconsistent generation of RES and EVs with RES can achieve mutual benefit enabling the power grid towards sustainability.

Interaction of EVs with solar photovoltaic and wind turbine

The literature study concluded that the interaction of EV with solar photovoltaic is beneficial from all respect of environmental, economic and technical viewpoint. It significantly reduces carbon emissions and fossil fuel usage. The appropriate energy management of EV and photovoltaic can increase the revenues for both photovoltaic suppliers and EV owners. Solar photovoltaic generates high power during daytime and can be used to supply the daytime charging demand of EVs. EVs can be utilized to absorb the excessive solar power generation and supply power to other loads during low solar power generation. Thus, the co-existence between RES and EVs bring about a positive impact and several studies have been conducted which are summarized in **Table 2**.

Wind energy harnessing has been developed due to their green nature and economic advantages. Many experiments have been carried out in different countries like Germany and Northeastern Brazil to assess the future wind energy utilization for EV charging (Hennings *et al.*, 2013; Borba *et al.*, 2012). Hennings *et al.* (2003) show that there are about 15% of excessive wind power generation by the year 2030 in Germany which can be utilized for EV charging purpose. Borba *et al.* concluded that the short-term interaction between EVs and wind energy generation is able to boost up the penetration of EVs into the market. Meanwhile, EVs can assist the regulation of wind generation intermittency in the long run (Borba *et al.*, 2012) (summarized in **Table 2**).

A number of investigations also have been conducted to examine the potential integration of EVs with solar photovoltaic and wind turbine altogether in the power grid and achieved 20% saving in the total energy cost (Berthold *et al.*, 2011). Fazelpour *et al.* (2014)

developed an intelligent optimization framework using Genetic Algorithms for design step of a practical grid-friendly parking lot. [Peas Lopes et al. \(2009\)](#) designed V2G controller in MATLAB software and can be utilized to maximize the RES integration in micro-grid (summarized in [Table 2](#)).

Automated Vehicles

Automated Vehicles are the most recent evolution in the transportation sector. Rapid development in communication, robotics and the need of catering the aging population in developed countries have potentially made AVs a necessity and a vital business paradigm ([Hong et al., 2008](#)). Uber is the current example which brought struggle for taxi companies to retain in business and remain competitive.

The first attempt towards driverless vehicles started in the early 1920s ([Weber, 2014](#)) and got momentum in the 1980s ([Fenton and Mayhan, 1991](#); [Ioannou, 2013](#)). Afterwards AVs were largely made in Germany and the U.S. during 1980–2000 ([Anderson et al., 2014](#); [Lantos, 2010](#)) and Google car brought AVs to the spotlight ([Guizzo, 2011](#); [Markoff, 2010](#)). Moreover, the automotive industry spends around €77 billion worldwide on R&D in order to nurture innovation and to stay competitive ([ACEA, 2015](#); [Nieuwenhuijsen, 2015](#)). Competition started between the giant car makers: BMW, Mercedes-Benz, Nissan, Google, General Motors ([Knight, 2013](#)).

For the developing countries, adoption of AVs may spare them the costs associated with expanding capital-intensive infrastructure, in similar way the mobile phone technology exempted them from expensive landline infrastructure ([Anderson et al., 2014](#); [Sridhar and Sridhar, 2007](#)).

In general, AVs operate on a three-phase design known as “sense-plan-act” which is the premise of many robotic systems ([Behere and Törngren, 2015](#); [DiClemente et al., 2014](#); [Siciliano and Khatib, 2008](#)).

The Society of Automotive Engineers (SAE) International ([SAE International, 2016](#)) taxonomy defines five levels of vehicle automation. In level 1 (driver assistance) and level 2 (partial driving automation), the human driver monitors the driving environment and is assisted by a driving automation system for execution of either the lateral or longitudinal motion control (level 1) or both motion controls (level 2). In level 3 (conditional driving automation), an automated driving system performs all dynamic tasks of driving (monitoring of the environment and motion control), but the human driver is expected to be available for occasional control of the vehicle. In level 4 (high driving automation) and level 5 (full driving automation) an automated driving system performs all dynamic tasks of driving, without any human intervention at any time. In level 4, the automated driving system controls the vehicle within a prescribed operational domain (e.g., high-speed freeway cruising, closed campus shuttle). In level 5, the automated driving system can operate the vehicle under all on-road conditions with no design-based restrictions.

The AV enhances fuel economy by 4%–10% because of its advance design and engine efficiency ([NRC, 2010](#)). Its implementation associated with a variety of positive societal impacts such as a safer transport system, a lower cost of transport as well as enabling a modicum of mobility to the non-ambulatory and disabled as well as to those in lower income households. It is estimated that the direct societal value that will be created will be between 0.2 and 1.9 trillion dollars annually by 2025 ([Manyika et al., 2013](#)). Such positive impacts are the driving forces behind the emergence of AV technology, making it a viable, economic model in the near future and beyond.

AVs also provide an opportunity for vehicles to communicate their maneuvers and actions with each other which may reduce idle time, improving both traffic and drive-cycle efficiencies ([Anderson et al., 2014](#)). The concept of “connected vehicles” (United States) or “cooperative ITS” (Europe) was known to the Intelligent Transport Studies (ITS) industry to resolve the communication and data sharing among vehicle-to-vehicle (V2V) and between Vehicle-to-infrastructure (V2I/I2V) and to improve the performance and safety of the automation system.

Implication of Travel Cost, Road Capacity and Travel Choices

The fixed costs of automated vehicles will very likely be higher than for conventional vehicles due to the advanced hardware and software technology involved. The increased fixed cost could influence the penetration rate and subsequently the magnitude of the effects of the automated vehicles. The Generalized transport cost (GTC), on the other hand, is expected to decrease because of lower effort, time, and money needed to travel. First, more travel comfort, enhanced travel safety, higher travel time reliability, and the possibility to perform activities other than driving (like working, meeting, eating, or sleeping) while on the move will likely lead to lower values of time. Second, less congestion delays because of increased road capacity and reduced (or even eliminated) search time for parking owing to self-parking capability, but also increased use of shared vehicles, would possibly require less travel time. Third, enhanced efficiency of traffic flow along with more fuel-efficient vehicles because of their lighter design (owing to less risk of having an accident) could also reduce the monetary cost of travel. Due to shorter headways, air resistance will possibly decrease; further reducing fuel use and costs. However, potential increase of vehicle travel demand because of enhanced road capacity, reduced GTC, and/or proliferation of vehicle sharing systems and urban expansion in the longer term, could compromise travel time and cost savings. The counter effects of increased vehicle demand could include increased congestion delays, longer trips, and more fuel costs ([Milakis et al., 2017](#)).

Implication Based on Ownership and Sharing, Location Choices, Land Use and Transport Infrastructure

Literature results suggest that shared automated vehicles could replace a significant number of conventional vehicles (from about 67% up to over 90%). The overall reduction of the conventional vehicle fleet could vary according to the automated mode

(vehicle-sharing, ridesharing, shared electric vehicle), the penetration rate of shared automated vehicles and the presence or absence of public transport. Few studies have explored the impact of automated vehicles on location choices and land use. According to their results, automated vehicles could enhance accessibility citywide, especially in remote rural areas, triggering further urban expansion. Automated vehicles could also have a positive impact on the density of economic activity at the center of the cities. Parking demand for automated vehicles could be shifted to peripheral zones, but could also remain high in city centers, if empty cruising of shared automated vehicles is not allowed. Moreover, several studies showed that shared automated vehicles can significantly reduce parking space requirements up to over 90%. Finally, because of automated vehicles the pavement-rutting damage could be accelerated. Still, the increase in speed of automated vehicles could compensate for such negative effect by decreasing rut depth (Milakis *et al.*, 2017).

Implication Comprises Energy Consumption and Air Pollution, Safety, Social Equity, the Economy, and Public Health

Literature results suggest that the use of automated vehicles can result in fuel savings and lower emissions in the short term. The net effect of vehicle automation on energy consumption and GHG emissions in the long term remains uncertain.

Various longitudinal, lateral and intersection control algorithms and optimization systems can offer significant fuel savings and lower emissions of NO_x, CO, and CO₂. Studies reviewed in this paper reported fuel savings upto 31% for longitudinal and lateral movement controllers and up to 45% for intersection controllers. Both fuel economy and emission reductions are reported higher as the penetration rate of vehicle automation systems increases. Furthermore, shared use of automated vehicles is associated with reduced emissions (VOC and CO in particular) because of the lower number of times a vehicle starts. One study (Greenblatt and Saxena, 2015) associated the long-term impacts of battery electric shared automated vehicles with up to 94% less GHG and nearly 100% less oil consumption per mile, compared to conventional internal combustion vehicles. Yet, several factors could lead to increased energy use e.g., longer travel distances and increased travel by underserved populations such as youth, disabled, and elderly. Thus, the net effect of vehicle automation on energy consumption and GHG emissions remains uncertain.

Many social factors are also uncertain like what could be the scale of job losses (or gains) due to full vehicle automation? Which sectors and which countries and/or regions would be most affected? And what could be the strategies to mitigate the economic impacts of expected job losses? (Milakis *et al.*, 2017).

Conclusion

In view of greenhouse gas emission reduction potential, advanced Vehicle systems, generally EVs are cleaner than the conventional Internal Combustion Engine vehicles (ICEV) as EVs have zero tailpipe emission. The RES integration with V2G technology facilitates to reduce the dependency on carbon intensive power generation and carbon footprint as well. Additionally, the smart grid provides economic advantages by numerous service and regulation to power grid.

On the other side the Advanced Vehicle Systems technology is not fully-matured, battery requires lots of research as it has restricted energy density, limited life cycle and high initial cost. Moreover, bi-directional V2G technology increases the EV charging and discharging cycles and accelerates the battery degradation. Battery life is a major concern for EV owners which may be a huge social barrier for V2G technology and EV deployment as well. Appropriate incentive-based policy can resolve this issue.

Charger technology and infrastructure are also point of concerns for EV deployment. Most of the EV chargers adopted in the market are uni-directional charger type. Bi-directional charger for V2G technology is under experimental stage. The EV deployment needs proper planning and huge investment cost to install complex infrastructure.

With the most recent advancement in Autonomous Vehicle (AV), a natural and organic synergy can be brought between shared AV fleets and EV technology to resolve the practical limitations of EVs including travel range anxiety, access to charging infrastructure and charging time management. Accordingly, the transportation sector can be more eco-friendly and economic. But AVs are also in stage of infancy. EVs and AVs need more maturity, further research and development to bring positive impact of vehicle advancement in economic and environmental aspect. Bottom line: Every citizen is responsible to reduce greenhouse gas emission; it also has impact while choosing transport system options. So, leave your car at home and hire cycle, walk or catch public transport. Also, don't forget about electricity.

Introduction

With the increase in greenhouse gases in the environment, the unpredictability along with fatal damages of the environment has significantly increased since the last two decades. The major production of greenhouse gases are through the combustion of fossil fuels. The major consumption sectors of fossil fuels are through Industries, Residential (electric power produced from fossils) and Automobiles. The air quality needs to be ameliorated which can be achieved by mitigation of content of Carbon products in the atmosphere. This can be achieved by using renewable and clean sources of energy. These include production of energy from Solar, Tidal, Geothermal and many more sources. However the use of Hydrogen as a clean fuel has been proposed as a very good alternative. Hydrogen as a clean fuel cell has been used in Proton Exchange Membrane Fuel Cells. However this approach is very uneconomic with cost of Hydrogen Fuel Cells in Engines exceeding almost 7 times the IC engines run by fossils and the reliability is a major concern in this field as well ([Chalk and Miller, 2006](#)). Hence this topic is under continuous research with advances in different sectors for tackling this situation.

So with advances in various fields for developing various techniques in order to enhance the use of renewable resources, advances were made in improving the storage capacities of energy obtained from renewable sources. These were done with the aid of Surface modification techniques using nano-materials, phase change materials, polymers, composites and paper based devices etc. Surface modifications of electrodes in Lithium ion based batteries and supercapacitors with the help of graphene, CNTs and other materials is under rigorous research as it has offered good alternatives to reduce the carbon content in the atmosphere.

With the advances in renewable energy is considered as one of the proposed viable solution to this predicament the renewable sources vary independently from the demand of the situation. Though their conversion techniques are becoming advanced and affordable. Nevertheless their contribution to sustainable energy will be decisive only when the storage methods are properly developed.

Microencapsulated Phase Change Materials (MPCM)

Phase Change Materials (PCM) are latent heat storage materials. They absorb or reject heat energy and instead of rise in temperature of the body the phase (gas, liquid or solid) of the body changes ([Hawladar et al., 2003](#)). They are used for storage of thermal energy. They are most suited in applications or regions where the energy storage is periodic or inconsistent. For instance their application was showed in the concrete walls to save thermal energy in an experimental setup in Spain ([Cabeza et al., 2007](#)). They offer many advantages in such a system. The Phase change temperature is almost equivalent to what is required in the system. The density of such materials is also very high. The Low density variation of these materials allows its efficient use. Thermal Conductivity is almost same in all phases. There is no undercooling. In addition to all these advantages the material is non-toxic, non-polluting and non-flammable. It is available at a cheap price ([Zalba et al., 2003](#)).

The Solid-liquid phase change PCM contained organic and inorganic materials. The organic materials provides chemical and thermal stability, good anti-corrosion properties and no undercooling takes place. However for inorganic materials the phase change enthalpy is very high. With the PCM offering so much advantages both from scientific and economy point of view, their uses are very high. However their use has been limited due to the lower thermal conductivity from several phases particularly when solidifying on the heat transfer surface ([Zalba et al., 2003](#)). This limits the heat power which can be extracted from this system. This reduces the efficiency of the system. Hence application of highly conductive metal fins were used in order to increase its efficient working. This increased the overall cost and weight of the system. Hence, a solution to such a problem was Phase Change Slurry. This Slurry contained PCM in the nano or micro phase. This slurry acts as a thermal energy carrier and thermal storage media. It provides the function of low temperature applications. These MPCM is composed of core PCM with polymer or inorganic shell to prevent the leakage and spilling of PCM during phase change ([Huang et al., 2011](#)). Good alternatives in microencapsulation are developed with much better performances. These include microencapsulate Paraffin, polystyrene, polymethyl methacrylate, polyvinylacetate, poly ethyl methacrylate, fatty acids, silica gel polymer, n-octadecane, polymethyl methacrylate and many more ([Hawladar et al., 2000](#); [Alkan et al., 2009](#); [Sari et al., 2010](#); [Ji et al., 2015](#); [Hariharan et al., 2018](#)).

So this is one of forms of engineering where the surface of materials is modified to improve the stability and the thermal energy storage.

Advances in Lithium Ion Batteries

In order to decrease the Carbon footprints from our atmosphere we need to limit the use of fossil fuels in our day to day life. A major consumption of these fossil fuels is in the automobile sector. This can be done by using vehicles which runs on electric

batteries or hydrogen. The vehicles running on batteries have been proved more efficient compared to hydrogen fuel cells vehicles in terms of cost and the net output work.

Lithium Ion batteries has found a lot of real life applications due to the rechargeable nature of its battery. It offers an advantage of a much lower discharging rate over other rechargeable batteries.

The Li ion battery contains a Carbon electrode, a positively charged metal oxide electrode with a lithium salt immersed in an organic solvent as an electrolyte. In order to achieve better performance of this battery many researches have been carried on in the field of materials science and surface engineering. The nanoscale materials and structures containing Carbon particles in the nano-dispersed phase possess higher charge storage capacity compared to normal carbon electrodes (Stephenson *et al.*, 2014). Hence researchers aim to efficiently produce such nano-materials at a rate which eventually reduces the overall cost of the rechargeable battery.

The cathodes contain an intercalation material which acts as a hold the Lithium ion. The lithium ion acts as a guest ion which can enter and leave the intercalation materials. The metal chalcogenides have acted as good materials which serve this purpose. These included TiS_3 and NbSe_3 . However LiTiS_2 offered high gravimetric energy as well as high life cycles compared to other intercalation compounds (Whiteley *et al.*, 2017). Transition metal oxides like LiCoO_2 is commercially used in many Lithium ion batteries. It is a very used transition cathode material because of low discharge voltage. It also possess high volumetric capacity, high specific capacity and has good cycling performance (Du Pasquier *et al.*, 2003; Graetz *et al.*, 2003). The main disadvantages of using this material is its uneconomic nature in the commercial market. The high price of this material is due to the presence of Cobalt in its compound. Not only it has low thermal stability but also its fast capacity fade at high current rates. The lower thermal instability of the material may have reduced its application in commercial sectors. Even deep cycles (extraction of more than 50% Lithium from the electrolyte) caused the distortion of the lattice of the material. Hence in order to overcome these difficulties surface engineering techniques were implied on these materials. Materials like Manganese, Aluminium, Iron and Chromium (Ceder *et al.*, 1998; Alcantara *et al.*, 1999; Madhavi *et al.*, 2002; Stoyanova *et al.*, 1994) were used instead of Cobalt or were doped with them. The problem was resolved on a limited basis. Nevertheless Coatings (a higher surface engineering technique) of metal oxides like Aluminium Oxide, Titanium Oxide and Zirconium Dioxide were used (Scott and Nicholls, 1980; Cho *et al.*, 2001). These metals ameliorated the mechanical and chemical stability of the battery as the chemically stable compound were formed which increased not only the structural stability of the material but also the side reaction with the electrolytes. This caused improved performance of the material even in deep cycling.

The surface engineering technique was best used when NMO ($\text{Li}(\text{N}_{0.5}\text{Mn}_{0.5})\text{O}_2$) electrode was developed with the help of using cheap Nickel replacing the costly Cobalt. The presence of Ni^{2+} ion in the cathode produce high pathways and very low strain (Kang *et al.*, 2006). Further application of this technique was used to involve Cobalt in the NMO electrode which improved the specific capacity of the electrode. The pure NMO electrode cannot be used as the Ni^{2+} ion substitutes the Li^{2+} ion. Further improvements were carried on in the field of intercalation materials by finding better materials and using improved surface engineering techniques and by using polyanion compounds.

With the use of materials such as Carbon Nano Tubes (CNT), graphenes and its components were used effectively as thin film current collectors (Zhang *et al.*, 2006). The thickness was less than 300 μm but it possessed high mechanical flexibility as well as high energy densities. However occasional electrolyte leakage took place which caused short circuiting of the device. Hence PVdF (polyvinylidene difluoride) was applied onto it (Lee *et al.*, 2013) because it is a highly non-reactive thermoplastic and has low thermal conductivity.

Conversion Cathode Materials are those materials which undergo solid state redox reaction while lithiation or delithiation. Lithiation is the incorporation of Lithium to an electrolyte in a battery. Metal salts of chlorides and fluorides can act as good conversion cathode material due to intermediate operation voltage and high specific and volumetric capacities. They suffer from poor conductivity, unwanted side reactions, large voltage hysteresis. Hence surface engineered materials were used where synthesis of nanoparticles of these materials were done. These materials were wrapped in conductive matrix to overcome the low conductivity. For instance FeF_3/CNT , $\text{FeF}_3/\text{grapheme}$, $\text{BiF}_3/\text{MoS}_2/\text{CNT}$ are some of the most efficiently used materials.

A hybrid sandwiched phosphorus-graphene(phosphorene) was synthesised by some researchers which showed remarkable specific and volumetric capacities (Sun *et al.*, 2015).

Anode material of these batteries include Carbon. The main reason behind it is that it is commercially usable even after 20 years of running. Carbon possess higher cycle life, more power density, moderate energy density and a relatively low cost. However the volumetric capacity of these electrodes are on a lower side.

Lithium Titanium Oxide is one of the most promising material for anode as it allows the superior combination of thermal stability, cycle life and high volumetric and specific capacities (Amine *et al.*, 2010) though it has high cost. These properties generate due to zero strain conditions during lithiation and delithiation cycles. This is because there is a maximum of 0.2% change in volume (Schamer *et al.*, 1999; Colin *et al.*, 2010). But the surface reactions are completely unavoidable. It undergoes gassing. This is due to the reaction between the active metal in the Lithium Titanium Oxide anode and the organic electrolyte (Belharouak *et al.*, 2012; Bernhard *et al.*, 2014; He *et al.*, 2015). This can be overcome by using proper surface engineering technique of coating the material with Carbon (Song *et al.*, 2014; He *et al.*, 2013). However coating with Carbon will cause the electrolyte to dissociate and form Solid-electrolyte interphase.

In order to overcome this Carbon composites were prepared by alloying it with different materials. It is so adopted because the alloying material have very satisfactory size for providing higher mechanical stability, transportation of electron and Lithium ions. Since the solid-electrolyte interphase expands in volume and needs to be stabilized, it is generally encapsulated within a carbon

shell with space inside it to provide volumetric expansion. Silicon and Tin has been used as an effective alloying component but a different approach was taken by some researchers to stabilize the solid-electrolyte interphase by adding some additives to the electrolyte. However Tin suffers from fracturing under moderate conditions (Qin *et al.*, 2014). But researchers showed that in-situ grapheme engineered Sn encapsulation is possible which provided very splendid results (Zhou *et al.*, 2015). The size of Sn varied between 5 and 30 nm. This was possible because of the high elasticity of grapheme material which caused the structural and interfacial stabilization of tin nanoparticles while subsiding the stress developed due to the volume change of the nanoparticles. This in-situ procedure was done by Chemical Vapour Deposition technique. This surface engineering technique of Chemical Vapour Deposition can be used for several materials like Nickel, Germanium, Gallium and even Silicon. Silicon has low delithiation energy, very high gravimetric energy, and chemical stability, low cost and also is non-toxic. A very unique material MoS_2 was used as a material to engineer the porous surface of the Carbon on order to render better working of the anodes (Luo and Zhi, 2015; Chang and Chen, 2011; David *et al.*, 2014). Their application was not only limited to batteries but also to supercapacitors due to their high retention power (Cao *et al.*, 2013; Tang *et al.*, 2015).

Supercapacitors

A supercapacitor is a capacitor which serves the purpose of high energy storage compared to normal capacitors. The use of supercapacitor is analogous to the use of flywheels in IC engines. Supercapacitors are amidst a battery and a capacitor in terms of energy storage i.e., more than a capacitor but less than that of a battery. However its quick charging capability and its ability to turn on quickly helps it to find its application in Hybrid vehicles, energy harvesting and smartphones. Supercapacitors use two layers of solid dielectrics to store energy. These are called electrochemical double layer capacitors. The supercapacitors use two mechanisms to store energy namely electrical double layer capacitance and pseudocapacitance (Conway, 2013). The electrochemical double layer capacitors uses carbon materials with high surface area where charge gets accumulated from the electrolyte/electrode interface. Pseudocapacitors use metal oxides or conducting polymers as the materials for electrodes for fast and reversible redox reactions (Zhang *et al.*, 2010). A high pseudocapacitance is not required because it makes the response time high capacitance decay rate (Liu *et al.*, 2010). Graphene based supercapacitors have been reported to have best serve the purpose of supercapacitors. This is because of the intrinsic capacitance of graphene is $21 \mu\text{F}/\text{cm}^2$. However its doping with different materials has improved supercapacitor properties. These include CNTs/graphene, metal oxides/graphene, etc. The formation of single walled carbon nanotubes as an electrode through zipping technique has allowed the electrode to have the property of individual single walled carbon nanotubes (Futaba *et al.*, 2006).

The use of conducting polymer based electrodes offer several advantages like its flexibility and its high conductivity. These material can be engineered to make very thin films which allows rapid energy release rate. The major disadvantage of such a capacitor is its cycle life. In order to increase the cycle life of these supercapacitors a surface engineered technique of formation of composites is used. The composite is made of the conducting polymer with the carbon nanotubes. This increases the volume, the porosity and the area for the swelling of the conducting polymer. This is done by co-deposition of several different conducting polymers in an ionic liquid (Snook *et al.*, 2011; Zhang and Zhao, 2009). Metallic Organic Framework composites with the incorporation of CNTs and graphene oxide has shown very exciting results for the researchers. The reason for their advanced results is the pseudocapacitance offered by the graphene oxide sheets (Ramachandran *et al.*, 2018; Rahmanifar *et al.*, 2018). Coleman *et al* found that the capacitance can be increased by increasing the thickness of the electrode. However this system fails to perform in a high rate capacitance. This failure was overcome with the surface engineering technique of introducing Carbon Nanotubes in the electrode. These carbon nanotubes not only removed such failure but also imparted mechanical stability to the electrodes. The incorporation of these nanotubes also improved the charge distribution in the electrode. This improves the intrinsic capacitance of the electrodes (Ling *et al.*, 2018; Nguyen and Gomes, 2019).

Conclusion

There is a dire need to reduce the percentage of greenhouse gases and the carbon percentage from the atmosphere. This can be done by limiting the use of fossil fuels in various sectors of our daily work. The use of fossil fuels needs to be limited because of the increasing global warming effects. However this cannot be done at the cost of sacrificing one's personal standard of living. Hence better, newer and efficient techniques needs to be formed or invented to form a stabilized environment. This article covered some aspects of how it can be achieved through the application of surface engineering techniques. There are many surface engineering techniques that are developed each day and implemented to give superior results compared to what has been found in the past. This article covered some of those techniques. The use of micro-encapsulating materials for their phase change is one of the ways to preserve the solar energy. This can limit the use of fossil fuels if the usage of these renewable energies increases. Another extensive but efficient way to decrease the carbon footprint is by using Hybrid vehicles or electric vehicles. These vehicles runs on batteries which can be surface engineered to increase the performance of the vehicles. The cathode and anode were doped and coated using materials which improved its cycle life and decreasing its commercial cost. The Supercapacitors were the next close thing to batteries which can also be used as their alternate. The use of graphene oxides and CNTs as thin films and dopants on the electrodes enabled them to

superimpose their own pseudocapacitance to the capacitance of the electrode materials. There are various other techniques of Surface Engineering which contributes to net reduction of the greenhouse gases and Carbon footprints in our environment.

Introduction

The alarming rates at which the fossil fuel reserves are decreasing and the steady rise in the energy requirement for the growing population attribute to the main driving force for finding alternative solutions to the prevalent conventional sources of energy. A shift towards the hydrogen economy from the carbon-based economy is a primary priority to counter the challenges of global warming. Combustion of all fossil fuels generates large amounts of CO₂, CO, SO₂, NO₂, CH₄ and all other greenhouse gases which is heating up the surface of the earth in an unprecedented rate resulting in temperature change and rapid ecological disbalance. One of the main concerns of the scientists since the past century has been the replacement of the conventional energy sources by renewable and environment-friendly sources of energy more commonly known as “Green Energy”.

Solar energy sector predominates the renewable energy economy. Concentrated research beginning from the early nineteenth century to date has established solar energy as an almost-conventional form of energy. Research reveals that the surface of the earth receives about 10²⁴ Joules of solar power annually (Chapin *et al.*, 1954) with the spectral range varying from 250 nm to 2500 nm in wavelength. The two commercially prevalent methods for converting solar energy are the use of photovoltaic cells and concentrating solar power with the aid of reflectors. The various ways by which solar energy can be used consolidate into the solar economy. PV (photovoltaic) technology used for the conversion of light to electricity directly, solar collectors, artificial photosynthesis for producing carbohydrates and hydrogen by the water-splitting method, biomass technology for generating complex carbohydrates to generate biofuels, etc., are the comprising units of the present solar economy (Bailey, 1972).

The relentless effort to establish solar energy as a sustainable form of energy resource has been alleviated with the inculcation of nanotechnology in the fabrication of the solar cells. The main reasons for embracing nanotechnology in the solar economy are the increased efficiency at a reduced manufacturing cost and ease of installation as well as fabrication. Moreover, nanotechnology also serves as the key to low-cost systems for generating, storing and transporting energy. Nanoscale level synthesis and designs combined with thin films offer economical solutions to the otherwise sophisticated methods of not only solar thermal systems but also for the other forms of renewable energy.

The present silicon solar cell-based technology, also known as the first-generation photovoltaic cell, dominates the economy with more than 86% of the global solar cell market. The second-generation of photovoltaic materials is comprised of thin film layers (1–2 nm) of semiconducting materials. Nanoparticles made of direct bandgap semiconductors are more commonly known as nanocrystal quantum dots. These serve as the basis to thin film solar cells on silicon or other substitutive conductive transparent oxide (CTO), such as indium-tin-oxide (ITO) substrate with nanocrystal coating. The prevalent researchers are extremely interested to explore the photo-catalyzed decomposition of pollutants at various Titania surfaces as well.

One of the basic pillars for establishing any technology as a sustainable one is the impact of that technology on the biotic as well as the abiotic environment. In spite of the huge promises that nanotechnology offers with respect to the solar energy sector, one of the most important underlying concerns remains largely neglected. Though advocated as green technology, the justification of it by exploring the various adversities that the nanoparticles offer is discussed in the literature review as follows.

Solar Cells

Evolution of Solar Cell Technology

First generation solar cells

The onset of developing solar energy as a potential substitute for fossil fuel began when Alexandre-Edmond Becquerel first observed the photovoltaic (PV) effect in 1839 (Yadav and Kumar, 2015). Since then a significant population of scientists has had devoted their studies for innovating the solar energy sector. Nevertheless, the first modern solar cell made of silicon was invented by Russell Ohl in the year 1946 (Yadav and Kumar, 2015; Castellano, 2010).

The initial photovoltaic solar cells were comprised of thin silicon wafers which function by transforming solar energy into electrical power. On the other hand, the working principle of the modern photovoltaic technology is solely based on the creation of an electron-hole in each cell composed of two different layers (p-type and n-type materials) of semiconductor material. In this type arrangement, when the p-type and n-type junction of the semiconducting material is struck by a photon carrying sufficient amount of energy, an electron is ejected with the aid of the energy gained from the impinging photon. The emitted electron then moves from one layer to another, thus creating an electron and a hole in the process and as a consequence of this movement, electrical power is generated (Srinivas *et al.*, 2015). The different types of materials used in fabricating photovoltaic solar cells are predominantly in the form of silicon (single as well as multi-crystalline, amorphous), cadmium-telluride, copper-indium-gallium-selenide (Srinivas *et al.*, 2015).

Fig. 1 Schematic diagram of crystalline Silicon solar cell.

The first-generation solar cells gained popularity for their significant high efficiency. The silicon wafer-based technology had been further classified on the basis of the number of crystals. The single or monocrystalline silicon solar cells were mainly synthesized by the Czochralski process (Srinivas *et al.*, 2015; Wurfel and Wurfel, 2009; Dmitrijev, 2006). Though the efficiency reached 17%–18%, yet the process of “recrystallizing” was expensive. The second classified category: polycrystalline silicon solar cells were composed of a wide variety of crystals generally coupled to one another in a single cell. The efficiency of this type of solar cells varied in the range of 12%–14%. Though lower efficient, the manufacturing costs for this variety being significantly lesser than the former one, the polycrystalline solar cells were considered economically feasible. Hence, they occupied almost 48% of the global solar cell production in 2008 (Saga, 2010) (Fig. 1).

Second generation solar cells

The primary motive for the invention of the second-generation solar cells was to diminish the huge disparity between cost and efficiency in the prevalent solar cells as much as possible. The chief constituents of the second-generation solar cells were the thin film and the amorphous silicon solar cells.

Amorphous silicon solar cells

The amorphous silicon thin film solar cells were the first solar cells that were manufactured on an industrial level. The thickness of the light absorbing layers of silicon wafer-based solar was approximately 350 μm thick, whereas the thin-film solar cells enjoy the advantage of very thin light-absorbing layers in comparison to the former, generally of the order of 1 μm thickness (Chopra *et al.*, 2004). The major advantage of using amorphous (a-Si) solar cells was the low manufacturing cost. Due to a considerable low processing temperature, various polymers and other suitable substrates suited the manufacturing criteria instead of using pure silicon which is way more expensive and thus the energy required for processing was vastly reduced (Imamzai *et al.*, 2012).

The low manufacturing cost made the a-Si solar cells widely available and popular. The word “amorphous” in regard to solar cell corresponds to the fact that the silicon constituents of the cell do not have a uniform alignment of atoms in the lattice that is they are non-crystalline in structure. The fabrication was done by coating the doped silicon material to the rear side of the substrate. While the conducting side had a silver hue, the reflecting side was in general dark brown in color (Sharma *et al.*, 2015). Though the efficiency and the cost of manufacture were compatible, the major problem was the lack of stability in case of efficiency. At PV module level, the efficiency dropped considerably. The efficiency of the prevalent PV solar cells ranges between 4%–8% at almost all conditions, including elevated temperatures or at conditions where the sunlight is available for a meager few hours (Maehlum, 2015).

CdTe solar cells

One of the leading candidates for the development of cheaper, economically viable photovoltaic (PV) devices is Cadmium Telluride. As a matter of fact, it also regarded as the first PV technology at a low cost (Yogi Goswami and Kreith, 2007; Luque and Hegedus, 2003). Possessing a band gap of ~ 1.5 eV combined with high optical absorption coefficient and chemical stability, Cadmium Telluride was a lucrative option for solar cell designing. Since CdTe is an excellent direct band gap crystalline compound semiconductor, the absorption of light is easier and thus making the efficiency higher. CdTe has a direct optimum band gap (~ 1.45 eV) and a high absorption coefficient of around $5 \times 10^{15}/\text{cm}$ (Elsabawy *et al.*, 2012). The efficiency of CdTe PV solar cells varies in between 9%–11% (Badawy, 2015). Though CdTe solar cells can be fabricated on polymer substrates and are flexible in nature, there are some serious environmental concerns. Cadmium which is regarded as heavy metal has been found to be

Fig. 2 Gold and silver cadmium telluride solar cell.

potentially toxic which can accumulate and cause serious harm to not only human beings but also animals and plants. Moreover, the disposal of Cd-based materials and their recycling is regarded as a highly sophisticated and expensive process as it poses serious threats to the environment and ecology (Maehlum, 2015). Therefore, the primary reasons to put CdTe solar cell technology to a halt were the serious disposal problems and the hazardous effects on the environment (Luque and Hegedus, 2003; Elsabay et al., 2012; Badawy, 2015; Sethi et al., 2011) (Fig. 2).

Copper indium gallium selenide (CIGS) solar cells

Copper, Indium, Gallium, and Selenium are the chief constituting elements of the quaternary compound semiconductor better known as CIGS (Andorka, 2014). CIGS falls into the category of important direct band gap type semiconductors. The efficiency of CIGS thin-film solar cell ranges about ~10%–12% which is higher in comparison to the CdTe solar cell efficiency. The higher efficiency range combined with more or less an environment-friendly nature are the two major reasons for favoring CIGS solar cell technology over the CdTe modules. Sputtering, evaporation, electrochemical coating technique, printing and electron beam deposition, etc., are the most widely used methods to fabricate CIGS PV solar cells (Razykov et al., 2011). The prolonged life-span without a much significant degradation is the specialty of the CIGS type solar cell (Badawy, 2015) (Fig. 3).

Third generation solar cells

Quantum dot solar cells

The solar cell design that utilizes quantum dots as the absorbing photovoltaic material are known as quantum dot solar cells. The primary motive behind this kind of solar cell is to replace bulk materials such as silicon, CIGS or CdTe. In bulk materials, the bandgap remains fixed. On the other hand, by changing the size of the dots, the bandgaps of the quantum dots can be tuned across a wide range of energy levels. In multi-junction solar cells, harvesting multiple parts of the solar spectrum is the primary principle. Thus, a wide variety of materials are used to enhance the efficiency of solar cells. Hence for this purpose, quantum dots perfectly fulfill all the required criteria.

Quantum dots are semiconducting particles which have radius lower than that of the Exciton Bohr radius. Similar to the energies of an atom, because of quantum mechanical considerations, the electron energies that can exist within them become finite. As a result of this, the Quantum dots are also referred to as “artificial atoms”. The sizes being the primary cause of the alteration of band gaps make quantum dots suitable for tuning the energy levels. A variety of bandgaps can be expressed with the aid of quantum dots which can be suitably grown over a wide range of particle sizes keeping the underlying material or construction techniques unchanged (Baskoutas and Terzis, 2006). In typical wet chemistry preparations, the synthesis duration or temperature are usually varied to achieve tuning of the quantum dots.

Colloidal Quantum dots (CQDs) synthesized by single junction methods using Lead Sulphide (PbS) are capable of being tuned into the far infrared and frequencies which are usually difficult to achieve with the prevalent traditional form of solar cells. A significant portion of the solar energy reaching the Earth is in the infrared spectrum while most of the radiation lies in the near infrared region. Infrared energy is made accessible as easily as any other spectral region with the help of colloidal quantum dots (Sargent, 2005). Moreover, the synthesis and preparation of CQDs are comparatively easier and faster. Though CQDs are usually synthesized in small batches, they can be mass-produced as well.

Distribution of the dots on a substrate is done majorly by spin coating, either by hand or by an automated process. Large-scale production generally uses spray-on or roll-printing systems which reduce the cost to a great extent. Expensive molecular beam epitaxy processes were used initially but later economically profitable fabrication methods like wet chemistry, solution processing

Fig. 3 Conventional CIGS solar cell model.

Fig. 4 Schematic representation of quantum dot solar cell.

methods, etc., were developed. Long hydrocarbon ligands help in stabilizing the concentrated nanoparticle solutions which help in keeping the nanocrystals suspended in solution. Since carrier recombination deteriorates the device performance due to the trap states present, engineering the nanocrystal surface chemically can better passivate the nanocrystals. An efficiency of 7.0% is achieved by following this process (Ip *et al.*, 2012). The use of iodide as a ligand that does not bond to oxygen was introduced in 2014 which was shown to maintain stability between the n- and p-type layers. As a result, the absorption efficiency got boosted, which thus generated a power conversion efficiency up to 8% (Shruti *et al.*, 2015) (Fig. 4).

Dye sensitized solar cells (DSSC)

Since the late twentieth century, the research has been primarily focused on increasing solar efficiency by not only manipulating molecular orientation but also use nanotechnology for harvesting light energy extensively (Li *et al.*, 2006; Zhan *et al.*, 2006; Graetzel *et al.*, 2012; Nozik, 2010; Suhaimi *et al.*, 2015; Liang *et al.*, 2007; Bertolli, 2008; Bagher *et al.*, 2015; see "Relevant Websites section"). The pioneer in the field of dye sensitized solar cell (DSSC) was Michel Gratzel from the Swiss Federal Institute of Technology (Bagher *et al.*, 2015; see "Relevant Websites section"). The DSSCs works on the principle of employing dye molecules between the various electrodes. The chief four components comprising the DSSCs are semiconductor electrodes in the form of

Fig. 5 Dye-sensitized solar cell.

n-type TiO_2 and p-type NiO , a dye sensitizer, redox mediator, and a counter electrode which can be either carbon or Platinum (Nozik, 2010). Simple conventional processing methods like printing technique are the primary method used to fabricate DSSCs.

The high flexibility, transparency and the low cost of production are the factors that make DSSCs a lucrative alternative to the solar cells of the previous generations (Bagher *et al.*, 2015). The photosensitization of nano grained TiO_2 coatings combined with the visible optically active dyes help to increase the efficiency of the DSSCs greater than 10%, thus making it suitable to be considered a novelty (Li *et al.*, 2006; Zhan *et al.*, 2006; Graetzel *et al.*, 2012; Nozik, 2010; Suhaimi *et al.*, 2015; Liang *et al.*, 2007). However, like all new technologies, it comes with the question of degradation of the dye molecules and hence issues concerning with stability are raised (Bagher *et al.*, 2015) (Fig. 5).

The poor optical absorption of sensitizers attributes to the questioned poor conversion efficiency. Unlike the quantum dot solar cells, the dye particles in DSSCs when exposed to the ultraviolet and the infrared radiations degrade which makes DSSCs unsuitable for use beyond a particular spectrum. Though coating with a barrier layer acts as a buffer and help reduce the degradation of the particles in the UV or IR region, it adds to the extra cost of the fabrication, thus making it economically unfeasible (Bertolli, 2008).

Perovskite solar cells

The class of compounds defined by the formula ABX_3 where X represents a halogen such as I^- , Br^- , Cl^- whereas A and B represent cations of different size are commonly known as Perovskites. The most recent discovery in the solar cell research community is the Perovskites and researchers are excited with this, in particular. Varied advantages over conventional silicon and thin film based solar cells helped the Perovskites gain huge popularity despite being a very new idea. The conventional Si-based solar cells are synthesized by high-temperature processes ($>1000^\circ\text{C}$) which are usually multi-step and are way more expensive than the methods employed for Perovskites and on top of that, fail to deliver efficiency at par with the manufacturing cost (Ahn *et al.*, 2015; Casey, 2015). The efficiency of the Perovskites solar cells reaches almost up to 31% (Shi *et al.*, 2015). According to an interesting investigation recently performed by Volkswagen, Perovskites have emerged as a potential candidate in the next generation electric-automobile batteries (Casey, 2015; Shi *et al.*, 2015). The stability and durability of the perovskite solar cells are the main

Fig. 6 Superstrate and Substrate configuration of perovskite solar cell.

drawbacks of the technology. Because of the degradation of the materials over time, the efficiency drops notably, hence questioning the durability of the solar cells. Moreover, the environmental impacts of Perovskites discussed later also contribute to the hindrance of commercialization (Fig. 6).

Environmental Impact of Alternative Photovoltaic Cell Technology

Effect of amorphous silicon solar cells

The Eco-indicator methods are the tools to assess the environmental impact of all the stages of the solar power generation process. The impact of a process on three specific fields: the effect to Human Health, the impact to the quality of Ecosystem, and the adversities upon Resource depletion are measured with the aid of this method (Goedkoop and Spriensma, 2000). Disability Adjusted Life Years abbreviated as DALYs are used to measure human health damages. Losing one life year by an individual is indicated by damage of 1, whereas a weight of 0.25 indicates four years of disability suffered by an individual. The study of DALYs comprises of mainly carcinogenic and respiratory effects on humans caused by organic as well as inorganic substances. Issues relating to climate change, ionizing radiation, and ozone layer depletion are also included in the studies of this method (Wasin et al., 2017).

Ecosystem Quality damages are measured in terms of PDF*m²*yr. PDF stands for "Potentially Disappeared Fraction of Species". It measures the extinction rate or the declination of the population of species in an area of land over a period of time. For the disappearance of all species within an area of one m² for one year, the rating is unity.

The measurement of ecosystem quality consists of detailed studies on ecotoxic emissions, the cumulative effect of acidification and eutrophication and reports on the land occupation as well as land conversion. The extraction of minerals and fossil fuels is quantified by "Resource Depletion". MJ surplus energy is the unit to measure the damage and represent the surplus energy required for future extractions of fossil fuels, compressed gases, and mineral resources (Wasin et al., 2017). To properly compare the categories of damage, an aggregation of various units into a single environmental impact function, known as an eco-indicator was implemented. By using a set of dimensionless weighting factors, the final result is being measured in terms of eco-points (Pt) (Henryk, 2011).

Tables 1 and 2 analyses the data used in the process of production of thin film amorphous silicon solar cell modules, for 1 kWh power generated. The input and output data related to the transportation stage were similarly obtained from solar cell power plant surveys and published literature concerning the production statistics (Chamsilpa et al., 2010). The consumption of fuel and emissions to the environment because of conveying the modules is discussed in Table 3.

Since, multi-crystalline photovoltaic solar cells require an electrical input, the consequence of this input results in the emission of nitrogen, oxygen, water vapor, nitric oxide, nitrogen dioxide, and NO_x. Whereas, in amorphous silicon solar cells, none of these gases are produced. This is because thin film amorphous cells do not require any electrical input. Table 4(a) and 4(b) quantifies the data used for analyzing the cumulative input and output for 1 kWh of power generation from solar energy.

Table 5(a) and 5(b) show that by recycling and reusing the material of old photovoltaic cells, there is a significant decrease in both energy consumption and material consumption. By constructing solar panels from old cells there is an energy saving of around a 1/3 when compared to using new materials (Richard, 2008). Furthermore, approximately 90% of the glass in an old cell can be recycled and used in new glass products (Monier and Hestin, 2011). Of the other recyclable materials, it was possible to reuse approximately 86.5% of them (Ancil, 2012).

Table 6 characterizes the summarised results for 1 kWh of power generation from solar energy. The impact of transportation and installation remained comparable to that of the generation of multi-crystalline PV solar cells. On the other hand, because of the recycling process, the environmental effects on a few impactful categories decreased. For example; the effects relating to change in climate, acidification or eutrophication, the respiration of inorganic as well as organic substances, and the extraction of minerals decreased by 53.33%, 50.57%, 46.68%, 25.09%, and 0.02% respectively solely because of recycling (Richard, 2008; Monier and Hestin, 2011; Anctil, 2012).

In spite of having lower waste generated and lesser harm done to the environment in comparison to the traditional crystalline silicon photovoltaic technology, the thin film amorphous silicon solar cells were unable to create a significant impact. The main reasons behind this were first, their low efficiencies given the higher requirement of land area for production and installation, and the second being, almost comparable consumption of resources with respect to multi-crystalline solar cells without much difference in results (Alsema *et al.*, 2006).

Effect of CdTe solar cells

The only thin film technology with costs lower than the conventional solar cells made of crystalline silicon in multi-kilowatt systems is the Cadmium Telluride photovoltaic solar cell (Gessert *et al.*, 2014; Zweibel *et al.*, 2008; David, 2008). Taking one lifecycle as the basis of calculation, CdTe PV potentially has the smallest carbon footprint, least water usage and shortest energy payback time of all prevalent solar technologies (Peng *et al.*, 2013; Fthenakis and Kim, 2010; de Wild-Scholten, 2013). The energy payback time of CdTe being less than a year accounts for the faster reduction in carbon emissions without short-term deficits of energy.

The toxicity of cadmium is a serious environmental concern which can be mitigated to a certain extent by the recycling of CdTe modules at the end of their lifetime (Fthenakis Vasilis, 2004). There are still uncertainties about proper recycling (Werner, 2011; Allen *et al.*, 2011) and the opinion, in general, is quite skeptical towards this technology (Trabish, 2012; Mullins, 2008). Cadmium being a rare earth material may also become a limiting factor to the scalability of CdTe technology at an industrial level in the near future.

The acute scarcity of tellurium – of which Telluride is the anionic form – is almost equivalent to that of platinum on the earth's crust thus, contributing significantly to the cost of the module (Woodhouse *et al.*, 2013). Despite the high manufacturing cost and the difficulty in availability of the raw materials required for production, CdTe technology is accounted for more than half of the thin film market in 2013 comprising of almost 5.1% of the global economy (Bagher *et al.*, 2015).

Cadmium is widely considered as one of the deadliest and toxic materials present on the surface of the earth. However, in terms of direct exposure, CdTe is apparently less toxic than cadmium in elemental form. This cannot be inferred to be harmless though. If ingested, Cadmium telluride is toxic in nature. It can cause serious respiratory and skin ailments if the dust is inhaled accidentally or if it is mal-handled (i.e., without wearing appropriate gloves and taking other necessary safety precautions). It has been recently

studied that the highly reactive surface of cadmium telluride quantum dots aggravates extensive reaction with oxygen thus causing potential damage to the cell membrane, mitochondria, and cell nucleus (Marco *et al.*, 2007). Thus, it cannot be concluded that the resulting toxicity is solely attributed to the cadmium content.

In addition to this, the recrystallization of cadmium telluride is typically done with the toxic compound of cadmium chloride. In the large-scale commercialization of cadmium telluride solar panels, the disposal and degradability are the major concerns. It has been recently suggested by scientists from the U.S. Department of Energy, Brookhaven National Laboratory, that large-scale use of CdTe PV modules does not present any significant risk to human health and the environment. Moreover, recycling the modules at the end of their useful life resolves a large portion of the environmental concerns. It has also been found that during their operation, these modules do not produce any pollutants, unlike fossil fuels, thus becoming an eligible candidate for green technology. Among all the present uses of cadmium, CdTe PV modules are apparently more environmentally friendly than the rest.

However, the approach of safety with respect to the use of CdTe in the European countries and China is, much more skeptical and cautious. In the European Union, cadmium and its compounds are identified as toxic carcinogens. Likewise, regulations in China allow all Cd products for export only. The issue of regulating the use of Cadmium Telluride is currently being discussed in Europe (see "Relevant Websites section").

Effect of quantum dots

The diversity involved in the synthesis of QD makes the topic of QD toxicity somewhat ambiguous. Hence, to avoid confusion, the first thing that should be considered is the difference in the physical and chemical properties of QDs with varying synthesis methods. The lack of studies based on toxicology, the varied concentrations of exposure or dosage of QD accounted in the scientific literature, combined with the widely varying physicochemical properties of individual QDs are the basic reasons why the studies of QD toxicity is anomalous.

Concentrates specifically intended for toxicologic appraisal (e.g., portion, term, recurrence of introduction, systems of activity) are not many. A large number of the investigations from which QD poisonous quality data is inferred and that have been referred to in reference to QD harmfulness were performed by nanotechnology specialists as opposed to toxicologists or well-being researchers. The greater part of the present investigations inspected here was intended to make inquiries concerning the physicochemical properties of novel QD items, for example, fluorescence, perceptibility, steadiness, and cell naming efficacy, not QD poisonous quality as such. Critically, and a potential wellspring of perplexity in surveying QD lethality, QD poisonous quality relies upon various components got from both individual QD physicochemical properties and natural conditions: QD estimate, charge, focus, external covering bioactivity (topping material, useful gatherings), and oxidative, photolytic, and mechanical dependability have each been appeared to decide factors in QD harmfulness.

For instance, some QDs have been observed to be cytotoxic simply after oxidative and additionally photolytic corruption of their center coatings. Last, in light of the fact that QD dose/introduction varies greatly in their units of estimation (e.g., milligrams per milliliter, molarity, milligrams per kilogram body weight, number of QDs per cell), associating measurement crosswise over current investigations is difficult. Despite the fact that the potential unfavorable impacts of nanomaterials on nature and human well-being have as of late been tended to by research activities sorted out under the National Science Foundation and the U.S. Ecological Protection Agency, no real data is presently accessible with respect to courses of QD introduction, QD security, aerosolization, half-lives, and how they parcel into natural media are right now ineffectively comprehended. Be that as it may, thought of introduction courses might be extrapolated based on what is known with respect to materials of comparative size and physicochemical properties.

Potential courses of QD introduction are hugely dependent on ecology, work environment, and helpful or demonstrative organization. Working environment exposures (e.g., engineers, analysts, clinicians) may result from inward breathing, dermal contact, or ingestion. For inward breath highways, a broad assemblage of toxicologic research exists on other nanoscale particles (e.g., asbestos, ultrafine particles) that may give an establishment from which approach to QD inward breath is considered. QDs differ in size, extending from around 2.5 nm up to 100 nm, contingent upon covering thickness and shift in their destinations of testimony in pneumatic tissues once aerosolized. For example, QDs < 2.5 nm may affect the lung and connect with the alveolar epithelium, while bigger aerosolized QDs get accumulated in bronchial spaces. Be that as it may, under what conditions QDs aerosolize and whether they structure totals in encompassing air are not known (Oberdörster *et al.*, 2005). Inward breath exposures may present potential dangers given that QDs have been appeared to be joined by means of endocytosis by an assortment of cell types and may live in cells for a considerable length of time extending up to months. The dangers due to exposures through dermal assimilation and unintentional ingestion may present is right now obscure.

The probable cause for significant concern through the course of introduction, given the social and monetary estimation of helpful/analytic QD items, are exposures coming about because of QD organization to people for restorative purposes. These sorts of exposures are at present hypothetical, as QD items are not right now endorsed for remedial/analytic purposes only. In any case, the potential for undesired/unforeseen impacts coming about because of the therapeutic/symptomatic organization of these materials likely will figure conspicuously in the improvement of medicinally based QD items. Their potential lethality by means of managerial courses of presentation is the very subject to a suite of variable and ineffectively gotten elements: QD toxico-and pharmacokinetics, toxico-and pharmacodynamics, and in vivo strength. It can be assumed that when QD energy and elements are quantified and proper kinetic analysis is made, the dangers presented by these exposures might be alleviated through quality control instruments (e.g., consistency and unwavering quality in volume creation), as they right now are with pharmaceuticals.

Exposures through ecological media (pollution) are a potential course of concern fundamentally as a result of QD metalloid center synthesis, and to some degree on account of QD center coatings. Numerous QD center metals (e.g., Cd, Pb, Se) are known to be dangerous to vertebrate frameworks at moderately low focuses (parts per million). Understanding the dangers presented by QDs in the earth is complex in nature, as poisonous quality differs broadly with the concoction condition of the metals, and natural change/debasement and parceling; which in turn will decide the dimension of the human wellbeing risk. As of now, nothing is known with respect to the soundness of QDs in the earth, item lifetimes, or how these materials segment into natural media. Presentation of QDs into natural media may happen by means of waste streams from enterprises that incorporate or use QDs and by means of clinical and research settings. Thus, transfer of QD materials and the dangers of spillage and spilling amid assembling and transport are potential wellsprings of concern. Ecological exposures are a significant hotspot for a few reasons: (a) the natural centralization of anthropogenic substances increments in direct extent to their utilization in the public eye, and given their wide scope of uses, QDs may see considerable change in generation volumes; (b) the half-existence of these materials might be very long (months to perhaps years); and (c) natural presentation will rely upon where these materials degrade (e.g., air, water or soil). As a result of the decent variety of physicochemical properties among the diverse sorts of QDs, almost certainly, illustrating ecological dividing will be troublesome. These are vital contemplations given that corruption of these materials in natural media, in the occasion they achieve ecological compartments, will without a doubt happen, and their rates of rot are probably going to be exceedingly factor, contingent upon both QD physicochemical qualities and the ecological media in which they segment.

Albeit little data right now exists with respect to courses of QD introduction, all courses depicted are of potential concern given QDs have been appeared to be fused into an assortment of cell types through endocytic components. Ebb and flow explore likewise recommends that there might be a danger of bioaccumulation of these materials (e.g., metals) in organs and tissues, as QDs have been appeared to live in cells for a considerable length of time to months and conceivably may give issues body troubles. Basic to all courses of introduction is the issue of QD soundness. For all intents and purposes, nothing is thought about QD digestion invertebrate creatures or their courses of discharge. In spite of the fact that QDs have been appeared to corrupt under photolytic and oxidative conditions, debasement items have not been identified/defined in vivo apart from the arrival of part center metals, for example, Cd and Se. It can be inferred, in regards to the courses of presentation, it is critical to recollect that not all QDs are similar; every individual QD type has its very own one-of-a-kind physicochemical properties that will direct its presumable course of introduction.

In vitro examinations recommend certain QD types might be cytotoxic. It was found that CdTe QDs covered with mercaptopropionic corrosive (MPA) and cysteamine was cytotoxic to rodent pheochromocytoma cell (PC12) societies at concentrations of 10 µg/mL (Lovric *et al.*, 2005). Uncoated CdTe QDs were cytotoxic at 1 µg/mL. Cell demise was the consequence of chromatin build-up and membrane blebbing, symptomatic of apoptosis. Cytotoxicity was increasingly articulated with lesser decidedly charged QDs (2.2 ± 0.1 nm) than with bigger similarly charged QDs (5.2 ± 0.1 nm) at equivalent concentrations (cytotoxicity controlled by MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] examination).

QD estimate was likewise seen to influence subcellular appropriation, with smaller cationic QDs confining to the atomic compartment and bigger cationic QDs limiting to the cytosol. The instruments engaged with cell passing were not known but rather were viewed as because of the nearness of free Cd (QD center debasement), free extreme development, or communication of QDs with intracellular segments prompting the loss of capacity. The impact of QD-instigated responsive oxygen species on cell demise was evaluated with N-acetylcysteine (NAC; a known inhibitor of Cd poisonous quality), cow-like serum egg whites (BSA), and Trolox (a water-solvent nutrient E). Both NAC and BSA yet not Trolox significantly diminished CdTe QD harmfulness, proposing that QD-actuated lethality might be in part initiated by Cd. Researches show that treatment with the QD topping material mercaptoundecanoic corrosive (MUA) alone (without QD) for 12 h caused extreme cytotoxicity in murine T-cell lymphoma (EL-4) cells at 100 µg/mL (Hoshino *et al.*, 2004a). A 12 h Treatment with cysteamine alone demonstrated weak genotoxic nature at 100 µg/mL. Henceforth, cytotoxicity was credited to QD topping material instead of the center metalloid complex itself (Hoshino *et al.*, 2004b). It is, notwithstanding, impossible that the danger seen can be exclusively ascribed to the QD coatings (MPA and cysteamine), as both size and charge and the impacts of NAC and BSA recommend something else (Lovric *et al.*, 2005). CdTe QD- instigated cytotoxicity appeared to be somewhat subject to QD estimate and might be expected to be a consequence of QD covering intracellular responses of the surface coatings, or intracellular debasement of QDs to metalloid particles. QD-actuated toxicity was observed in the MUA-covered CdSe/ZnS QDs which were seen to be cytotoxic to HeLa cells and essential human hepatocytes at centralizations of 100 µg/mL (MTT measure) (Shiohara *et al.*, 2004).

A few in vitro and in vivo investigations have been referred to in the writing as showing an absence of proof for QD-instigated cytotoxicity (Hoshino *et al.*, 2004a; Ballou *et al.*, 2004; Dubertret *et al.*, 2002; Jaiswal *et al.*, 2003; Larson *et al.*, 2003; Voura *et al.*, 2004). But a couple of the above examinations do propose that QDs can influence cell development and suitability. QD micelles, CdSe/ZnS QDs in a hydrophobic center of n-polyethyleneglycol phosphatidylethanolamine (PEG-PE) and phosphatidylcholine, brought about cell variations from the norm (feasibility, motility) when infused into *Xenopus* blastomeres at convergences of 5×10^9 QDs/cell (~ 0.23 pmol/cell), though cells infused with 2×10^9 QDs/cell displayed a typical phenotype and were said to be factually like un-injected developing lives (Dubertret *et al.*, 2002). Henceforth, QD cytotoxicity was additionally observed to be portion subordinate (Hoshino *et al.*, 2004a). EL-4 cells brooded (10^6 cells/well) with concentrations varying in the order of 0.1, 0.2, and 0.4 mg/mL of CdSe/ZnS- SSA QDs displayed a dose- reaction relationship on a 24 h basis. Cell reasonability diminished at QD fixations above 0.1 mg/mL, and practically all phones brooded with 0.4 mg/mL were nonviable past 6 hr period. Curiously, roughly 10% of EL-4 cells held QDs following 10 days of culture. The fluorescence force (QDs) of cells slowly diminished and was exceptionally amassed in

endosomes, proposing intracellular corruption of QDs. Despite the fact that cytotoxicity was seen at 0.1 mg/mL in vitro, EL-4 cells brooded in 0.1 mg/mL SSA-conjugated QDs, and in this way infused into naked mice, were not identified to be dangerous in vivo. Another resulting study (Lovric *et al.*, 2005) watched reversible DNA harm in WTK1 cells (comet measure). DNA harm was noted after 2 h of treatment with 2 μ M QD- COOH (carboxylic corrosive), yet after 12 h, QD-actuated DNA harm was effectively fixed.

Thus, it can be proposed that QD poisonous quality relies upon different variables derived from both the intrinsic physicochemical properties of QDs and ecological conditions. QD measure, charge, fixation, external covering bioactivity (topping material and practical gatherings), and oxidative, photolytic, and mechanical solidness are each factor that, all things considered, and independently, can decide QD harmfulness. Of these physicochemical attributes, practical covering and QD stability of the core unmistakably and likely are the significant factors in evaluating the danger of QD poisonous quality in certifiable presentation situations.

Effect of perovskites

The life cycle assessment (LCA) approach is implemented in the following studies on one agent i.e., tin-based PSC, which has been accounted for to reach up to 6.4% of intensity change efficiency (Noel *et al.*, 2014) along with two lead-based perovskites cells (Espinosa *et al.*, 2015). The three structures investigated are (a) Glass-ITO/PEDOT:PSS/lead-perovskite/PCBM/Al (You *et al.*, 2014), (b) Glass-FTO/TiO₂/lead-perovskite/Spiro-OMeTAD/Ag (Liu *et al.*, 2013) and (c) front terminal (FTO) Glass/minimal TiO₂/tin-perovskite+ mesoporous-TiO₂/Spiro-OMeTAD/Gold (Hao *et al.*, 2014). The areas of investigation primarily incorporate the extraction of fossil fuels for the production and installation of the PSC modules. The other primary areas of investigation in the arena of PSC modules include (1) landfill and (2) incineration succeeded by incomplete recuperation of metals. The practical unit for this survey is taken to be a supply of 1 kWh of energy, being required by 114.89 cm² of light harvesting area (yearly insolation of 1700 kWh m⁻² and 80% of execution proportion or performance ratio).

The Life Cycle Data System (ILCD)26 strategy was chosen to evaluate other natural effects of tin-based PSCs and contrasted it with the effects of two toxic PSCs. Results demonstrate that the creation of a practical unit of tin-based PSCs devours more energy than lead PSCs and it presents bigger ecological effects, for the most part, brought about by its low efficiency. The evaluation of the energy and lifecycle discharges of the tin-based PSC reveal that the epitomized energy per useful unit is 124.1 MJ kWh⁻¹ and the identical measure of CO₂ is 9.4 kg kWh⁻¹; the two qualities practically two fold than those for the lead-based PSCs. The tin-based PSC has bigger ecological effects than both toxic PSCs in almost all classifications. Specifically, tin-based PSCs score multiple times higher in resource consumption than the other PSCs where the FTO is in charge of $\approx$ 40% of this effect (mostly from tin production) and the back-anode represents $\approx$ 60% (due to the expensive means for extraction of gold, where the related mining process has a high ecological effect, particularly for open-pit mining).

To match the production of one functional unit, tin PSC requires twice the land area than that of the other lead-based PSCs, due to their lower efficiency. The only mean by which this difference between the two categories can be reduced is a noticeable improvement in the power conversion efficiency of tin-based PSC. In case of environmental change, the ascent in efficiency ought to be 12.4%, for human lethality 28% and 109%– malignancy and noncancer impacts, respectively– and an increase in 55% in efficiency for having comparative resource exhaustion scores. If hypothetically, silver is considered as the back anode for tin-PSC, rather than gold, the expected proficiency to rival lead-PSC would be 12% in all shown classes, aside from resource depletion which would be 24%. Despite stability being the main drawback, the lead-based PSCs do offer promising results in low cost compared to the existing technologies (Hwang *et al.*, 2015).

With respect to the impacts of lead on human toxicity, effects of tin are negligible in the sphere of both malignant and benign effects of this impact category. The major concern with lead lies in the stage where the life cycle of the lead-based PSCs end. The European restriction on hazardous substances (RoHS) (Bagher *et al.*, 2015) is the amount of lead which is limited by weight in any homogeneous material. If the mixture of TiO₂with perovskite and spiroOMeTAD as a homogeneous layer is considered, the lead content is 0.55% for the tin-based PSC (Green *et al.*, 2014). In this case, the percentage slightly exceeds the already established RoHS limit. Due to the fact that the finish of-life for the perovskite solar cell is as yet an unexplored field, and can bargain the security of this new innovation, diverse courses are yet to be analyzed before concluding straight away.

In the first transfer situation, the cells are landfilled, while in the second situation the cells are burned including the recuperation of lead from the cinders. At the point when the cells are landfilled, the lead is produced to the earth through draining impacts also known as leaching (Spalvins *et al.*, 2008). In the most pessimistic scenario, it is viewed as that up to 70% of lead will be extracted in the first year (Hailegnaw *et al.*, 2015). The second situation is the point at which the combustion of cells takes place and the lead is recouped from the debris (Nagib and Inoue, 2000), where 98% of lead is recuperated by treating it in a basic solution.

To account for recycling benefits, the most common approach is that of calculating “environmental credits”. This method employs substitution of the newly produced materials along with the recycled materials which are coined as “environmental” credits. It has been assumed that the inherent properties of the recycled materials are unchanged and have the same properties that they possessed before combustion. Thus, the recycled products are safe enough to suitably replace the original materials (ISO, 2006) The recovered energy from materials from the incineration processes is regarded as an “environmental” credit which acts as a suitable alternative to the energy produced from conventional sources of energy.

The human health (cancer and noncancer effects) and fresh water, and resource depletion are the most affected categories due to both manufacturing as well as recycling of the PSCs. The impact of perovskite layers is 36.8% on malignancy and human toxicity, followed by the waste treatment of polyethylene terephthalate which holds for about 28.4%, the front electrode comprising of 15.9% and 12.8% in case of back electrode. Because of the small amount of lead that the solar cells are comprised of, lead recovery is not very feasible. An innovative approach suggests that these lead PSCs after use can be utilized as lead-storage devices,

thus averting pertinent problems like lead disposal and/or extraction at the end of the life cycle, etc. According to a section of the scientific community, these devices can be transformed into long-term storage cells for lead especially the ones that have been recycled from car batteries (Li *et al.*, 2015; Chen *et al.*, 2015).

In spite of the pressing concern of higher toxicity of lead over tin as individual elements, the latter suffers from drawbacks too many to be considered as the ultimate photovoltaic technology. Though Tin is almost 6.3 times more expensive than lead, (LME) yet it is the third most critical metal in strategic energy technologies. Tin production is fairly concentrated, taking place mainly in countries with high political risks, such as China, Indonesia, and Peru, which together make up about 82% of the world in supply thus questioning the availability of the metal throughout the world (Moss *et al.*, 2011). It is apprehended that the terrestrial ecotoxicity and global warming contribution due to the tin can be ten times more than that of lead (Voet *et al.*, 2013). Thus it can be said that though PSC is a very promising candidate to replace all the existing solar-based technology, yet needs a significant scientific breakthrough to stay true to its promise.

Conclusion

The biggest drawbacks that hindered the growth of traditional silicon-based photovoltaic cell generation were the total cost involved throughout the manufacturing, transporting, installing processes and the adversities that the technology burdened the environment with. These very reasons gave the scientists and technologists a drive to develop cleaner technologies as suitable alternatives to the existing PV cell sector. Along the course of this article, various limitations of these inventions have been identified.

Just after a few decades of analyzing the derogatory side of crystalline Si PV cells, thin film amorphous silicon cell technology came into being. The apparently cost-friendly amorphous cell technology suffered its major setback when the efficiency of the cell in question failed to be compatible with the area of land it required for manufacturing and the number of natural resources it consumed for production as well as recycling.

Similarly, the other second-generation solar cell technology viz Cadmium Telluride cells or CIGS cells could not mark a significant impact. On analyzing the environmental perspective, Cadmium which is identified as one of the most toxic elements on earth poses danger not only from the degradability point of view but also is considered a notorious carcinogen. Moreover, the scarcity of the element also made this technology an economically unfeasible one. Stringent laws in regards to the manufacture and regulatory duties dealing with Cadmium make the mentioned technologies almost skeptical for commercialization.

Perhaps the most promising alternative to the traditional PV cell technology is the Quantum Dot Cell. One of the chief concerns regarding the eco-friendly nature of QDs is the usage of Cadmium and selenium, two of the most widely used constituent metals in QD core metalloid complexes. These two metals are widely known to be the cause of acute and chronic toxicities in not only vertebrates but are also capable of considerable human health and environmental derogation. Since QDs are comprised of highly engineered nanomaterials, the toxicity of each type varies with both inherent physicochemical properties and environmental conditions. The size, charge, concentration, outer coating bioactivity, oxidative, photolytic, and mechanical stability all play key roles in the variance of QD toxicity. Since generalization is not possible in the case of quantum dot cell technology, further concentrated researches are required to be conducted in details as the QDs definitely do not qualify to be environmentally absolutely harmless.

The final topic of discussion was the analysis of the much-popularised Perovskite Cell technology from a “clean technology” frame of reference. The two main types of perovskite cells discussed in this review were tin-based and lead-based cells. Though the toxicity of lead is higher than tin, the lead-based perovskite is less harmful than tin PSC. The reason being the usage of comparatively harmless lead iodide in the former one. A detailed optimization study has to be conducted with the other forms of PSCs like gold, OPV, etc to assess holistically. It has also been discussed on how incineration has advantages over landfill at the end of the PSC life cycle.

Though the most recent technology in the form of Quantum Dots and Perovskites exhibit adversities and a toxic facet, yet it is believed that troubleshooting is possible. If researchers and scientists work extensively on eradicating the small but unmistakable environmental and economic concerns, then the optimism with which these technologies rose to prominence will not go in vain.

The vision with which the renewable energy especially solar energy was developed over the years was considered almost successful with the significant lower carbon emission associated with manufacturing, installing and using the alternative solar cell technology. But what scientists termed as “hidden carbon footprint” or “Carbon debt” along with effects on the other environmental aspects are to be very cautiously scrutinized. An overview of a few highlighted environmental issues due to the usage of the alternative PV cell technology has been discussed in this article. Detailed and more in-depth research related to the mitigation of environmental hazards can surely bring about a path-breaking change in the future commercialization of alternative photovoltaic energy.

Application of Remote Sensing in Wind Resource Assessment

Siraj Ahmed and Prem K Chaurasiya, Maulana Azad National Institute of Technology, Bhopal, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

The high-quality wind measurement is a fundamental and pressing need in wind energy industry particularly at higher heights as well as in hilly and complex terrain. The modern wind turbines are becoming bigger and higher, reaching into the unknown turbulence and wind regimes in the atmosphere. It is essential to assess the availability of wind resource before starting the wind project in terms of atmospheric characteristics that may generate turbulence, power production and for a successful return on the project investment (Pena *et al.*, 2015).

The mast mounted cup anemometer is only accepted and calibrated sensor for both wind resource and power performance testing. However, the increase in turbine size has exposed the challenges related to cup anemometer measurement-point measurement i.e., it is important to place the cup anemometer at wind turbine hub-height, with increase in turbine's height cup anemometry measurement and instrumentation becomes expensive, cumbersome and logistically complex affair. Additionally, the present practice of measuring power performance on a single hub-height point measurement is not technically representative for large swept areas. So, to mitigate this challenges wind energy industry requires multi-height and volume measurement strategy for measuring wind distribution at the tip of the turbine blade as well as over the entire rotor of wind turbine (Courtney *et al.*, 2008). The remote sensing instruments can play a significant role in mitigating above challenges and can be used as an alternative technique for meteorological mast erection.

The most promising, accurate and quantitative remote sensing techniques for wind energy measurement includes sound and light wave propagation and backscatter detection based instrument for example SODAR, LIDAR, Scatterometry and SAR. The SODAR (Sound Detection and Ranging) and LIDAR (Light Detection and Ranging) are direct measurement and works on the principle of Doppler shift, scatterometry works on proxy-empirical calibration methods. The remote sensing instrument can serve wind energy sector for a number of purposes such as Wind resource assessments, wind park development projects, Power curve measurements, Bankability, Wind model and wind resource (wind atlas) uncertainty evaluation (Pena *et al.*, 2015). Furthermore the recent and improved developments have helped wind energy industry to integrate wind LIDAR directly into wind turbine blade, hub and spinners. These developments extended the performance of LIDAR for enhanced wind turbine yaw control, lead-time control for individual pitch control, prolonging the wind turbine longevity, protection against fatigue.

Wind lidars in the market for vertical mean and turbulence profile measurements are available based on two different measurement principles i.e., Continuous wave (CW) lidars Pulsed lidars. Several wind lidars are commercially available in the market. CW based wind lidars are manufactured by Natural Powers (ZephIR) and OPDI Technologies & DTU Fotonik (WINDAR) while Coherent Technologies Inc. (Wind tracer), Leosphere (WindCube), CatchtheWindInc (Vindicator) and Sgurr Energy (Galion) manufacture pulsed lidars. There are several sodar manufactures on the wind RS market today including for example Remtech, Atmospheric Systems Corporation (formerly Aerovironment), Metek, Scintec, Second Wind Inc. and Swedish AQ System to mention the most dominant.

This article presents the brief overview of different remote sensing technique used in wind energy sector along with the case study, measurement campaign conducted at the southern part of India.

Remote Sensing of Wind

Light Detection and Ranging (LiDAR)

It is an active ground-based optical remote sensing instrument that transmits the electromagnetic signal and then analyzes the backscattered signals that are received back to determine the information of atmospheric particle from which the electromagnetic energy or waves scatter. The light signals strike the atmospheric particle such as water droplet, dust, pollen and salt crystals that are suspended and travelling along at the speed of the wind. The speed of wind can be determined by detecting the change in backscattered wave's frequency. It measures data across ten user-defined heights up to 300 m and measures fifty data across 360-degree scan every second. The frequency of the emitted light (f_E) is reflected back to the receiver (f_R) changes due to the interaction with the moving aerosols particles available with the wind. The change in frequency - its Doppler shift (Δf) can be measured as

$$\Delta f = f_R - f_E \quad (1)$$

and the speed of the aerosols in the line-of-sight of the laser orientation (V_{LoS}) can then be calculated as

$$V_{LoS} = -\Delta f \times \lambda \quad (2)$$

where λ wavelength of laser emissions.

The Fig. 1 below shows the working principle and components of ZephIR 300 Wind LiDAR.

Fig. 1 (a) Working principle and (b) different components of ZephIR 300 Wind LiDAR.

Wind LiDAR for measurements are available based on two measurement principles i.e., Continuous Wave (CW) LiDARs and Pulsed LiDARs.

Continuous wave (CW) LiDAR

The CW LiDAR emits a continuous beam of laser at a measurement height and the backscatter beam is detected due to Doppler shift. The measurement range and spatial resolution is controlled by the focal properties of the telescope as well as for the multi height measurement the CW LiDAR adjusts its telescope. This LiDAR system operates in the telecommunications near-IR band around $1.55 \mu\text{m}$. Motion of the target in the beam direction causes change in the frequency of the light via Doppler shift. This shift in frequency is correctly measured by the return signal and the resulting beat is sensed by the photodetector at the different frequency. CW LiDAR is a simplest form of LiDAR which operates at a given range by beam focussing and wind profiling is done by continuously scanning the beam. The output signal is digitized by an analogue to digital converter, after that Fast Fourier Transformation (FFT) generates a Doppler spectrum and at last the value line of sight wind speed can be evaluated using velocity estimation algorithm (Pena *et al.*, 2015; Courtney *et al.*, 2008).

Pulsed wave LiDAR

In pulsed wave lidar the laser pulses are transmitted into the atmosphere and are scattered due to the presence of small dust particle. The pulsed wave lidar uses the optical heterodyne detection for the measurement of wind and aerosols entrained in the atmosphere. A pulsed LiDAR has a continuous wave laser, known as master oscillator to generate the local oscillator beam as well as to generate the powerful transmitted pulse. The master oscillator supplies the laser wavelength, the laser line width, the laser intensity noise and the state of polarization. The pulsed laser sends cyclic pulses of high energy. The pulse time period is some hundreds of nanoseconds, that determine the length of the pulse in the atmosphere and so the spatial resolution. Once the pulse leave the laser, the detector starts to detects the backscatter signal from the range gates. The pulse first crosses the telescope optics and produces a zero Doppler signal which is used as a reference for the zero distance. The collected signal from each pulse provides the total wind speed information (Pena *et al.*, 2015; Courtney *et al.*, 2008; Lang and McKeogh, 2011).

The key difference between Continuous Wave LiDAR and Pulsed LiDAR are as follows (Table 1):

Sound Detection and Ranging (SODAR)

Sodar is an acronym for Sound Detection and Ranging and has commercially been used in the wind industry since 1980 for various purposes such as micrositng, wind resource assessment, wake measurement etc. The advances in SODAR technology have enhanced the accuracy and reliability of SODAR systems. SODAR is a ground based remote sensing technique works on Doppler principle. SODAR transmits a short acoustic sinusoidal 'chirps' (a sound beam) vertically upward into atmospheric boundary,

Table 1 Key difference between CW and Pulsed Wave LiDAR

Parameters	Continuous wave LiDAR	Pulsed wave LiDAR
Velocity accuracy	Restricted by the coherence time	Restricted by the pulse duration
Range gate	Determined by focus, increases as R^2 increase	Constant around $CT/2$
Number of range gates	Less than 10	More than 100
Laser source	1000 mW laser	10 mW and 200 mW power amplifier
Linear polarization	Not necessary	Essential
Maximum range	Few hundred of meters	To some kilometers

Note: Pena, A., Hasager, C.B., Badger, M., *et al.*, 2015. Remote sensing for wind energy. DTU Wind Energy. DTU Wind Energy-E-Report-0084 (EN). Courtney, M., Wagner, R., Lindelow, P., 2008. Commercial lidar profilers for wind energy: A comparative guide. In: Proceedings of the European Wind Energy Conference, Brussels, Belgium, (April).

**Fig. 2** Second wind TRITON SODAR.

while at the same time the backscattered chirps is reflected back to the receiver. The wind speed, direction and turbulent structure depending on sonic frequency, system's power output, atmospheric stability and existing noise environment are determined by using intensity and Doppler shift of the returned signals at lower atmosphere approximately 2 km. The mono-static phase array SODAR is mostly used for wind resource assessment. The amount of backscattering results from turbulent fluctuations is about half of the wavelength of the sound pulse. This scattering is known as Bragg scattering. The power of the signal received by the receiver is a function of the emitted power and the scattering that occurs. The power received by the receiver can be mathematically written as (Pena *et al.*, 2015; Lang and McKeogh, 2011):

$$P_R = P_0 \frac{A_R}{R^2} L_v e^{(-2r\alpha)} \sigma(R)_E \quad (3)$$

Where, P_R is the received power, P_0 is the transmitted power, α is the atmospheric attenuation, A_R is the effective area of the receiver, L_v is probe length $\sigma(R)_E$ is the scattering cross-section at range r . The term $P_0 A_R L_v$ can be described as a 'system function' which is specific to each SODAR (Fig. 2).

Commercial SODAR devices are available in a various configurations:

Monostatic phased array SODAR

These SODAR systems have an array of transceivers, arranged in a rectangular framework. A phase delay between transceivers and the emitted sound chirps in a particular direction make a SODAR listen to provide a signal.

Similarly, Monostatic multiple independent antennas SODAR utilize three or more transceivers to emit sound chirps and record the backscattered sound signal. The antennas are configured such that the three components of the wind can be acquired using a multi-beam.

Bistatic phased array SODAR

Bistatic SODAR uses a separate transmitter and receiver to explore the atmosphere. Both the transmitter and receiver scan the vertical volume to provide vertical component of the wind field. In other hand the transmitter can transmit vertically and the receivers can alter their azimuth to measure at different elevations.

Scatterometry

The Synthetic Aperture Radar (SAR) is an instrument that processes the backscattered signal but only wind speed measurements can be retrieved. Radar scatterometers, operates at different sub-bands of the microwave range of electromagnetic spectrum and are used to draw near-surface wind speed and direction over the ocean from sun-synchronous satellites.

Mitigating Greenhouse Gas and Carbon Footprint

The concern to decrease greenhouse gas emission is gaining a huge attention globally. Carbon dioxide is one of the major constituent to accelerate greenhouse gas emission. The various countries have initiated several policies to minimize the carbon emissions, such as encouraging development of renewable energy and technical innovation in renewable energy sector. The renewable energy like wind power, solar and biogas may provide an alternative opportunity to reduce greenhouse gas emission and global warming issues through restricting the utilization of conventional energy resources. According to the report of Global Carbon Project, last year (2017) China produces 27% of global emissions, United States accounts for 15% of emissions, the European Union 10% and 7% is emitted by India. China's emissions are projected to go up 4.7%, United States emissions are expected to increase 2.5% and India's emissions are projected to rise 6.3% in 2018.

The greenhouse emission can be reduced by identifying the sources of emission, which can be obtained by proper measurement, monitoring and corroboration of GHG emissions. A Carbon footprint can be measured by undertaking a GHG emissions measurement or other calculative activities denoted as carbon accounting. Once the volume of a carbon footprint is acknowledged, a strategy can be devised to reduce it, e.g., by technological developments, use of green energy sources, reduction of fossil fuel consumption, appropriate waste management and recycling to save material cost and energy, carbon offsetting and others. Carbon Footprints can be reduced through the development of alternative projects, such as solar and wind energy, which are environment friendly, renewable resources, or reforestation. These examples are known as Carbon Offsetting, the counteracting of carbon dioxide emissions with an equivalent reduction of carbon dioxide in the atmosphere.

Among all the sources of green energy, wind energy has an immense potential to reduce GHG emissions. Also, wind energy has a small environmental footprint when compared to others energy supply resources. Wind energy has taken a commanding lead among other renewable energy sources. The wind energy resource assessment plays a significant role in estimating wind potential and contributes to a more secure energy supply. The advanced ground-based remote sensing techniques like SODAR and LiDAR measures wind speed at higher heights as well as at complex terrain accurately and efficiently. This advanced technique provides additional environmental benefits, management and site characteristics for wind farm project development along with reduced greenhouse gas emissions. The remote sensing technique further decreases the cost and reduces wind energy's footprint. The production of electricity using wind energy reduces considerable amount of CO₂ emission in the environment, if the same power is generated using conventional sources of energy. Application of remote sensing techniques can mitigate considerable amount of GHG emission.

A Case Study at Kayathar, India

Site Detail

The wind resource measurement was conducted at Kayathar, situated at southernmost part of India (latitude 08° 57' 44.27" N and longitude 77° 43' 10.80" E). The terrain has a gentle slope in western direction and the roughness length of the site is 0.03 m with open farm land, few trees and buildings (Ahmed, 2015) and the annual average temperature at the site is 38°C and relative humidity of the site 72% respectively. The measurement is done at two heights i.e., at 80 m and 100 m using ground based SODAR and LiDAR instrument.

The Table 2 illustrates the mean wind speed, standard deviation, kurtosis and skewness by both the techniques. The Fig. 3 shows the location of site on the map of India.

In this study, 10 min average time series wind data at a height of 80 m and 100 m from 01 September 2014 to 30 September 2014 are used for evaluation of Weibull parameter, wind characteristics, turbulence and shear factor. This case study also presents an economic comparison between remote sensing instrument and meteorological mast. The time series wind data were collected simultaneously by Cup anemometer mounted on 120 m long lattice structure meteorological mast, SecondWind Triton SODAR and Zephir 300 continuous-wave wind LIDAR profiler for the same period of time and at same height mentioned above.

Comparison of Wind Characteristics

Wind speed

The comparative analysis of wind speed between met mast technique and remote sensing technique for the recorded data is shown in Figs. 4 and 5. The Figure shows the daily mean wind speed at 80 m and 100 m respectively. It can be seen from Figs. 4 and 5 that SODAR and LIDAR measurement follows the comparable trend as of cup anemometer. The mean wind speed measured by LIDAR

Table 2 Statistics of measured wind speed data at Kayathar

Height	Assessment technique	Mean wind speed (m/s)	Standard deviation (m/s)	Median	Skewness	Kurtosis
80 m	MAST	8.330	4.2137	9.258	−0.2686	1.8709
	SODAR	7.989	3.9734	8.971	−0.2964	1.8142
	LIDAR	8.647	3.6212	9.501	−0.3916	2.3344
100 m	MAST	8.446	4.4178	9.488	0.1014	5.1747
	SODAR	8.351	4.0388	9.340	−0.3161	1.8970
	LIDAR	9.019	3.6339	9.993	−0.5167	2.5001

**Fig. 3** Geographical location of Kayathar.**Fig. 4** Comparison of daily mean wind speed profile at 80 m.

is higher whereas SODAR measure lower wind speed as shown in Table 2 which can be due to different medium (light and sound) adopted to detect wind speed.

The Fig. 6 (a) and (b) shows probability distribution function of measured data for both the technique. It is observed that the remote sensing measurement shows discrepancy with met mast measurement at both the heights due to wind driven wave

Fig. 5 Comparison of daily mean wind speed profile at 100 m.

Fig. 6 (a) Comparison of remote sensing technique with met mast. (b) Comparison of remote sensing technique with met mast.

distorting the intensity of the sound beam and light beam. It is seen that SODAR measurement shows better performance at both heights.

Estimation of weibull parameter

Weibull distribution is a significant tool to estimate wind energy potential and to express the wind speed frequency distribution. The Weibull is a two parameter distribution function and is represented by a dimensionless shape parameter k and scale parameter c in units of wind speed (m/s) and it can be described by its probability density function $f(v)$ and cumulative distribution function $F(v)$ as given below (Chaurasiya et al., 2018, 2017a).

$$f(v) = \frac{k}{c} \left(\frac{v}{c}\right)^{k-1} \times \exp\left[-\left(\frac{v}{c}\right)^k\right] \quad (4)$$

$$F(v) = 1 - \exp\left[-\left(\frac{v}{c}\right)^k\right] \quad (5)$$

where v is the wind speed, k is the dimensionless shape parameter, and c is the scale parameter having the same unit as v (m/s). This case study involves the estimation of Weibull parameter from both the techniques along with the statistical analysis to prove the effectiveness of result. The Weibull parameter is estimated using nine different numerical methods for each instrument at both the heights.

The meteorological mast is used as a standard instrument in wind energy sector for monitoring wind parameter, furthermore this study indicates that remote sensing measurements follows the same trend as of meteorological mast measurement for the measurement of both scale and shape parameter. There were no major difference between the computed parameter of k and c from SODAR and meteorological mast (Figs. 7–12).

The SODAR measurement has a mean absolute percentage error of less than 10% at both heights where as LIDAR measurement has a higher error in the computed values of k and c (Table 3).

Fig. 7 Weibull distribution at 80 m measured from MAST.

Fig. 8 Weibull distribution at 80 m measured from SODAR.

Fig. 9 Weibull distribution at 80 m measured from LIDAR.

Fig. 10 Weibull distribution at 100 m measured from MAST.

Wind power density and characteristics

Wind power density shows the total available energy at the site for conversion, which can be calculated as (Ahmed, 2015):

$$\frac{P}{A} = \frac{1}{2} \rho c^3 \Gamma \left(1 + \frac{3}{k} \right) \quad (6)$$

The Table 4 below summarizes the calculated wind power densities and wind characteristics i.e., most probable wind speed (V_{mp}) and maximum energy carrying wind speed (V_{me}) by both the measuring instrument at measurement heights. At a given location the peak of wind speed probability distribution is shown by most probable wind speed, whereas the peak of wind power probability distribution is shown by maximum energy carrying wind speed. The value of V_{mp} and V_{me} can be calculated from the following equations (Ahmed, 2015)

$$V_{mp} = c \left(1 - \frac{1}{k} \right)^{\frac{1}{k}} \quad (7)$$

$$V_{me} = c \left(1 + \frac{2}{k} \right)^{\frac{1}{k}} \quad (8)$$

Fig. 11 Weibull distribution at 100 m measured from SODAR.

Fig. 12 Weibull distribution at 100 m measured from LIDAR.

Table 3 Comparative statistical analysis of remote sensing technique

Height (m)	SODAR				LIDAR			
	R^2	RMSE (m/s)	χ^2	MAPE (%)	R^2	RMSE (m/s)	χ^2	MAPE (%)
80	0.9878	0.0033	0.0107	6.1755	0.9291	0.0152	0.2072	12.713
100	0.9636	0.0054	0.0293	7.4799	0.8427	0.0182	0.2661	17.232

Turbulence and shear analysis

The high sensitivity and different signal processing technique, data analysis strategies of ground based remote sensing techniques has made it possible to measure shear and turbulence at different heights along rotor. The later techniques can also be used for formulate and analyze rotor equivalent wind speed which is considered to provide more accurate and representative power curves particularly for bigger machine with large rotor diameter.

In this study the vertical wind speed models are used to extrapolate wind speed at higher heights. The comparison of the vertical wind speed profile measured from SODAR is compared with power law (Verhoef *et al.*, 2009) and the log law (Verhoef *et al.*, 2009)

Table 4 Wind power density estimation using Weibull parameters

Height	Measurement technique	Experimental value	Characteristics wind speeds (m/s)	
		Wind power density (W/m^2)	V_{mp}	V_{me}
80 m	MAST	658	6.67	13.13
	SODAR	568	6.52	12.44
	LiDAR	623	6.77	13.65
100 m	MAST	702	6.63	13.49
	SODAR	622	6.99	12.70
	LiDAR	671	6.82	13.03

**Fig. 13** Comparison of vertical wind speed profile (a) power law (b) log law.**Fig. 14** Vertical profile of turbulence intensity.

Table 5 Comparative payback period and AEP

Parameters	Formula	Heights				Unit
		80 m		120 m		
		MAST	SODAR	MAST	SODAR	
Turbine capacity	TC	2000	2000	2300	2300	kW
Capacity factor	CF	20	20	20	20	%
Annual energy production (Y)	$Y = TC \cdot CF \cdot 8760 \text{ h/year}$	3,504,000	3,504,000	4,029,600	4,029,600	kWh/year
Total electricity generation(20 year)	$V_{\text{tog}} = Y \cdot 20$	70,080,000	70,080,000	80,592,000	80,592,000	kWh
Export fraction	F	100	100	100	100	%
Total cost (V_{tot})	$V_{\text{tot}} = (T_c + O_c + W_c + W_m)$	143,560,000	145,750,000	179,970,000	176,125,000	INR
Unit cost of electricity generation	$G_c = V_{\text{tot}}/ V_{\text{tog}}$	2.048	2.079	2.233	2.185	INR
Payback period	$P_b = V_{\text{tot}}/ A_{\text{exp}}$	12.08	12.27	13.17	12.89	Years
Total saving	S	–	–	–	3,868,416	INR

Table 6 Comparative saving in GHG emission using remote sensing technique

Parameter	Coal	Wind power using remote sensing technique	
Grams of CO ₂ equivalent per Kilowatt-hour of electric energy	955	at 80 m 21	at 100 m 21
Electric generated	3,504,000	3,504,000	4,029,600
Grams of CO ₂ equivalent generation	3,346,320,000	73,584,000	84,621,600
Saving of grams of CO ₂ equivalent per Kilowatt-hour of electric energy		3,272,736,000	3,261,698,400

along with mast measurements. The power law model is commonly used for defining vertical profile in wind energy. It is observed from the Fig. 13 that the SODAR-derived mean wind speed profile fits well with both power law and log law. The little deviation can be observed mainly due to the influence of wind-driven wave. It is also seen that the variation between the SODAR measurement and standard vertical wind profile is dependent on mean wind speed, higher mean wind speed results in higher deviations.

The mean value of turbulence intensity decreases initially at 60 m and 80 m height, above then it increases due to mechanical friction. The turbulence intensity measured by SODAR was poorly correlated with meteorological mast, the correlation were reasonable. Further study is required to facilitate accurate measurement of turbulence intensity using SODAR. The Fig. 14 suggests that there is exponential descend in the value of turbulence intensity with decrease in height.

Economic and GHG Emission Aspects

The new and recent advances in remote sensing techniques have made it possible to reduces GHG emission and economically feasible for the project. But aside from the price of instruments, accurate measurement with validation, project duration and other legal proceedings are necessary to make it bankable and attract the investors.

This case study shows the economic comparison of the approximate cost of wind resource monitoring done through traditional meteorological mast and SODAR at 80 m and 120 m height. Additionally, it also discusses the saving in GHG emissions using remote sensing techniques. This economic calculation assumes no incentive or loan, grant, discount rate and wind farm land rate. By using SOADR system the unit cost of electricity generation reduces to 2.14% and payback period to 2.12% compared to mast measurement (Chaurasiya *et al.*, 2017b). Hence, by adopting SODAR system for wind resource assessment it is possible to reduce the total cost of the wind project without degrading the superiority and performance of wind turbines and it is also possible to attain a payback period of less than 20 years (Table 5).

The Table 6 shows the saving of GHG emissions using remote sensing techniques in wind energy sector. From Table 6, it can be seen that by using remote sensing techniques a significant amount of emission is saved as compared to conventional energy source.

Conclusion

Today, remote sensing techniques are properly calibrated, accurately aligned, installed and maintained and their signal processing concepts are well interpreted as well as the volume-averaged wind measurement provides information in all the three direction at each point at discrete hub-heights, are indeed accurate and technically representative wind measuring instrument. Remote sensing

instrument are very much capable of matching the wind industry's demand and can be used as supplement to high mast tower for wind profile measurement and wind resource assessments. The application of remote sensing technique in wind energy resource assessment reduces the greenhouse gas emission and carbon footprint to higher extent and can lead to mitigate challenges in global warming.

Before, remote sensing wind measurements can become fully certified and accredited to wind industry standards, new and revised IEC standards have first to be set and come into effect. However, the measurement campaign shown in this study clearly provides the insight ability of ground based remote sensing instrument. All the parameters measured from the ground based remote sensing instrument were found to be approximate closer to the tall meteorological measurements.

Introduction

Bioenergy consisting of solids, liquids, semi liquids or gas-based fuels are usually of bio (organic origin). Liquid fuels may be exploited directly for various energy needs as transport fuels for the roads, rail lines, and as aviation fuels for the air transportation. Other uses may include applications in various types of engines, turbines, electrical power generators and several other energy conversion operations. Gaseous and solid energy fuels can be applied in the area of electrical power production for direct and indirect purpose designed power plants; in boilers and other power utilities (heavy and light current incorporated). Chemical and end products are usually elicited from several organic matter produced by solid and liquid fuels as by-products. Subsequently, more chemicals and more energies can be produced from the use of flora/organic derived materials and feedstocks, animal residues, urban/commercial by-products and wastes and agricultural residues or forestry products. Resources from biomass are mainly of primary, secondary or tertiary sources. Resources from primary biomass are directly produced through photosynthetic processes. These photosynthetic energy processes are of direct land-based uptake by short-rotation perennial woody plant/crops, herbaceous produce, oil crop seeds, energy crops, algae, and post agricultural residues of forest products, trees, crops of all kinds including leaves of plants/trees, switch grasses, wheat straws, all manner of corn residues, bark/pericarps from trees, shells and so on. Secondary biomass resources on the other hand, are products of primary biomass resources processing which may be directly derived including products like: bagasse from sugar cane, saw dust/residues from mills or chemically-derived in the case of coal tar, waxes, bio-oils, glycerols, black liquors, lignin from paper/pulping processes. They may also be biological in the production of energy for example in the case of excreta production by animals and may include cow dungs, poultry droppings and the likes. Resources from tertiary biomass are residues from post-consumer spills, for example: greases and fats from animals, waste cooking or vegetable oils, packaging wastes, domestic/kitchen wastes, grey water, debris from demolition and construction sites and others.

But several pre- and post- conversion technologies have been developed in recent years for the conversion of various biomass resources into direct energies, heat, power and fuels for several domestic and industrial application in virtually all the countries of the world. Conversion technologies of biomass may be classified under three or more processes according to several authors: direct combustion process, biochemical processes and thermo-chemical conversion processes. In all three processes, energy conversion technologies will have to be concerned with the feedstock having the potential of variability in energy and mass densities, moisture content, sizes, sustainable supplies. It is therefore imperative that modern technologies to be adopted are all encompassing to include hybridising conventional fuel/biomass technologies which may employ fossil fuels for some operations such as preheating, drying and constant fuel supply maintenance as back up in the event of interruption of biomass supply during this developmental stages. Tateishi (2016) in YANMAR Technical review presented four biomass conversion technologies to include carbonisation and biodiesel production. European Biomass Industries Association (EUBIA) in the most recent technical report highlighted instead to include direct combustion; anaerobic digestion; oil extraction for biodiesel; fermentation for alcohols; pyrolysis for biochar, oil and gas production and gasification for CO and syngas rich in hydrogen (EUBIA, 2018). These are encapsulated in Fig. 1 which also gives a general overview of modern conversion technologies with their attendant end-products.

Energy derived from biomass is presently taking over the total energy use in most countries and in the United States, it is almost one third. The contribution to the energy mix are accounted for by biomass energy production technologies. Of the predominance of the conversion technologies, biomass combustion technologies is the most dominant source of the energy production from biomass in Europe and United States. Research and development are currently harnessing biomass resources for various renewable energy technologies. Aside biomass combustion, gasification technologies and or biochemical processing, biomass carbon sequestration has been developed as another milestone potential for capturing carbon emission for storage and utilisation and for mitigation of climate change currently plaguing the world over.

Carbon sequestration and storage from combustion of conventional fossil fuels in recent years have been developed as a means of eliminating climate change, curtailing emissions and creating more renewable energies. It is a known fact that emissions of CO₂ and CO from biomass resources or fossil fuels as a consequences of combustion can be sequestered. Biomass energy from carbon sequestration as a carbon sink has net negative impact which would also deliver free form of energy for electricity, hydrogen and heat. Energy from biomass is no doubt neutral, negative or positive depending on biomass resource in juxtaposition with land availability. Therefore regeneration of the biomass by replanting or the release of carbon during/after combustion is recaptured and the energy scheme in itself becomes normally carbon (CO₂) neutral (Schlamadinger *et al.*, 2001). Also the possibility of the carbon released from biomass conversion being sequestered and stored is achievable in geological deposition which is very much analogous with carbon sequestration and storage. With this type of technology in place, the feasibility of displacing fossil fuels, removing atmospheric CO₂ and reduction of CO₂ emission on sustainable and continuous cycle has been attained.

Fig. 1 Overview of Several Biomass Energy Conversion Technologies. *Source:* European Biomass Industry Association, EUBIA, 2018. Biomass Processing Technologies, EUBIA, Brussels. Tateishi, T., 2016. Development of High Efficiency BP-G 300kW-Class Biogas Co-Generation System. YANMAR Technical Review, Research and Development Management Division.

The recovery of concentrated stream of CO₂ from emissions and flue gases is simply a matter of splitting atmospheric CO₂ and N₂. Chemical adsorption is an option using amines. There are also membrane separation, cryogenic distillation and solid–solid adsorption using molecular sieves. It is also possible to eliminate air-borne nitrogen (N₂) before combustion and subsequent recycling of the flue gas into combustion in order to thermally control overheating of the system. Chemical adsorption has proven itself the most effective and promissory capturing approach. Adsorption by amines involves the use of monoethanolamine (MEA) due its high CO₂ carrying capacity. Almost 90% of the 13% concentration of air can be captured and sequestered (recovered) from flue gases. The carbonation of biomass by hydrothermal cracking process can bring about the sequestration of CO₂. The product of hydrothermal cracking as a carbonized by-product–hydro-char possesses huge potential in the sequestration of atmospheric carbon. Any biomass can be a feedstock for this process. The amount of emissions of CO₂ from biofuel combustion are estimated to be equal to the same amount sequestered in biomass which makes the whole process carbon neutral.

Biomass Carbon (CO₂) Sequestration (Bio-CCS)

Carbon sequestration can be defined as a process of long term capturing and removing of atmospheric CO₂ and its other forms to mitigate and defer global warming. This is done through biological, chemical and physical methods or mechanisms including artificial mechanisms which includes algal CO₂ sequestration; it involves producing biomasses by capturing CO₂ with some photo-synthetic mechanisms to produce energy (Eloka-Eboka and Inambao, 2017). Atkin *et al.* (2012) noted in their study that the act of sequestering is solely dependent on the nature of carbon sink achieved through several methods and forms. For example, directly by chemical reactions which are inorganic and can result into CO₂ in the various forms of salts: carbonates and bicarbonates, bonding with other dissolved minerals and salts. This chemical chain forms compounds such as Ca and Mg carbonates. Storing CO₂ and other forms of carbon can indeed assist in mitigating the varying effects of greenhouse gases. Additional income can also be generated by forest land-owners from storing carbon on their managed forestlands. There are already research and development activities in place in integrating or fusing several energy schemes into carbon capture and sequestration technologies, giving rise to energy products with net negative ambient carbon emissions. The attention of a technology development of this nature is focused primarily on the need to provide an approach that will reduce carbon emissions drastically from the mix of non-renewable energy resources. The strategic mechanism culminates from the compatibility of the existing energy infrastructures for transformation. The technology can be integrated in juxtaposition with biomass energy systems.

The application involves that ambient carbon which are in biomass during production are captured and sequestered - taken away from the atmosphere for biomass production thus there is a net carbon sink or negative net emissions if any. This technology is still evolving, but several factors accounts for its attractiveness. These include: (a) Net reduction in ambient/atmospheric CO₂ from bio-CCS systems which provides strategies for offsetting emissions from anywhere in the climate economy; (b) Limited and efficient land and water resources utilisation of the system; and, (c) Availability of current conventional systems and facilities for Bio-CSS and so there is no need for installation of new technological facilities. The process of photosynthesis combined with solar energy, air and water, forms glucose that is stored within living plant tissues. Microbes are classified as autotrophs by deriving their energy from the sun through photosynthetic chemical reactions or processes. Through microbial putrefaction of biomass, plants

and animal materials and tissues are broken down to form carbohydrate compounds, organic acids, proteins, waxes, coal oil, shale oil, natural gas and humic substances. It is the autotrophs which are responsible for fixing CO₂, to make their own food fuelled by the light energy from sun (photoautotrophic), or through oxidation of nitrogen, and sulphur (chemoautotrophic). Chemoautotrophic include: the cyanobacteria, green sulphur bacteria, purple sulphur bacteria and purple non sulphur bacteria. It is important to mention that sulphur based bacteria use sulphide of hydrogen as hydrogen donor instead of using water as in a photosynthesis and by cyanobacteria (Atkin *et al.*, 2012).

A number of motives and factors that the scientific and research communities have identified and advanced in the containment of CO₂ emissions. CO₂ is the primary contributor in the evolution and emissions of greenhouse gases, therefore its control as an emission is not insufficient in restricting the continuous global increase of temperature to below 2°C as contemplatively demanded by IPCC (Le Quéré *et al.*, 2009). Carbon emissions can be effectively controlled and minimized by sequestering them into solid biomass of micro- and macro-algae (Eloka-Eboka and Inambao, 2017). There are a number of authors who have conducted extensive research on this technological concept such as (Shabani, 2016; De Lary *et al.*, 2012; Zheng *et al.*, 2012; Ponnuswamy *et al.*, 2014). The production and growing of algae has been identified as the main process by which the sequestration of carbon can be achieved. There are a number of other studies which have been conducted to highlight the impact of CO₂, level and concentration as a source material in the production of algal biomass, nutrients, food and lipids. Among the researchers whose studies are enlisted include: (Singh and Singh, 2014; Hu *et al.*, 2014). Activities such as burning of fossil fuel, deforestation and power generation which are classified as anthropogenic being human induced contribute to the precarious growth in greenhouse emissions and gases (GHG). The USAEPA estimates that about 70% or more of greenhouse gas emissions are contributed mainly by transport, other energy consumption (domestic and industrial) and production in just 2010. It also reported that since 1990–2010, the trend was increasing at a rate of 34%–35% (Wilbanks *et al.*, 2012; Wilbanks and Fernandez, 2014). CO₂ levels have tremendously increased since the pre-industrial revolution till the present as reported by Rahaman *et al.* (2011) and Singh and Ahluwalia (2013).

Although CO₂ is essentially an indispensable gas in photosynthetic processes and industrial applications, its unending increase is threatening the entirety of the eco-system and thus increasing global warming further due to its longer atmospheric e-decay lifespan and retention of between 50 years to 200 years (Van Den Hende *et al.*, 2012; Turns, 2012). It is the principal contributor to global warming. Due to the urgency of reducing greenhouse gas emissions and to avert environmental disasters attributed to global warming. The world community of nations and leading 37 highly industrialized countries and the European community adopted the Kyoto protocol on 1997 (Kyoto Protocol, 1997) in an attempt to reduce greenhouse gases by 18% between 2013 and 2020 (Cheah *et al.*, 2015; Yoo and Al-Attayah, 2013). Besides the effort by international community and individual governments in trying to contain increase in greenhouse gases, the scientific and research communities have been looking at carbon sequestration of biomass feedstock or from micro- and macro- algae. Micro-algae have long been recognized as an alternative to biodiesel fuel production. This is intended to reduce utilisation and overdependence on fossil fuels, thus reducing significantly greenhouse gas emissions and accumulation. Micro-algae are considered to be photosynthetic efficient in the conversion of the CO₂ biochemically, produce high biomass, high lipid accumulation and valuable other non-fuel co-products as reported by Xie *et al.* (2014), Eloka-Eboka and Inambao (2017). Micro-algae have a very high potential to deal with carbon dioxide emissions. They provide almost 10%–50% times more efficiency in cleaning CO₂ as compared to terrestrial plants (Cheng *et al.*, 2013; Lam *et al.*, 2012; Anjos *et al.*, 2013; Zhao and Su, 2014; Kao *et al.*, 2014). It should be mentioned also that the contribution of terrestrial plants to reducing CO₂ emissions is 3%–6% globally (Ho *et al.*, 2011; Kao *et al.*, 2014).

During photosynthesis, CO₂ is used as a carbon source and converted into organic compounds through solar power energy. In micro-algae nutrition, carbon is the primary source of nutrition with nitrogen and phosphorous in that order (Lam and Lee, 2011; Aziz *et al.*, 2017; Choong *et al.*, 2017). Micro-algae are a very strong agent in the bio-sequestration of CO₂ where dried micro algae alone contains 50% of carbon derived from CO₂ (Lam *et al.*, 2012) and approximately 1.83 kg of CO₂ fixed for every 1 kg of micro-algae biomass produced (Jiang *et al.*, 2013; Kumar *et al.*, 2015; Clares *et al.*, 2014). According to biomass in the world energy supply of electricity, heat and transportation fuel accounts for 8%–15% and 33%–50% respectively of the current world consumption of energy by the projections of 2050. In addition to increase in demand for wood fuels (Huotari *et al.*, 2015), the demand for bioenergy is also increasing. The agricultural sector is the leading contributor of biomass wastes such as shells, pits, fruits, seeds, coir, bagasse, fodder, pulps, and cake from different plant species in the sector activities. This wastes have a potential to be used as biofuels (Barbanera *et al.*, 2016; Buratti *et al.*, 2016). Agricultural biomass is also richer in fertilizer elements such as K and P compared to wood biomass (Vassilev *et al.*, 2013a,b). It has come to be generally accepted that biomass is a renewable energy resource that does not contribute to the development of greenhouse gas due to their CO₂ conversion being neutral. Agricultural biomass is highly alkaline and enriched with alkaline earth components thus significantly contributing to the capture of CO₂. This is done through formation of carbonates due to solid gas reaction of CO₂ released during the burning or atmospheric Ca, K, Mg and Na oxyhydroxides formed during combustion of biomass (Vassilev *et al.*, 2013a).

In discussing carbon sequestration, it is imperative to remember that although it carries advantages and is receiving global attention, in environmental active carbon pools like oceans, care must be taken to avoid exchanging one environment solution to another since this can create a transferable problem to another environment (Lackner, 2003). The use of fossil fuel globally exceeds 5000 gigatonnes of carbon (GtC) (Rogner, 1997) as compared to global consumption of 6 GtC annually. However, towards the 2050 and beyond, stabilization of atmospheric CO₂ concentration and maintaining a healthy economic growth in the global economy, will require the world to adopt carbon neutral energy that will surpass current world energy consumption projections

(Hoffert *et al.*, 2002; Hernandez *et al.*, 2015). It is crucial to remember that the energy sector is vital and key in mitigating climate change and greenhouse gas emissions (Intergovernmental Panel on Climate Change, 2007). If the world community wants to achieve the aims and objectives of carbon sequestration, it has to operate on a multiterawatt scale according to (Lackner, 2003) while trying to carbon sequester. There are two factors which heavily affect and impact on carbon sequestration, storage time and storage capacity. These two factors affect biomass sequestration and CO₂ utilisation, due to the limitation for example of oceans to absorb carbonic acid relative to carbon resources (Lackner, 2003). However underground injection becomes the simplest and effective technique for carbon sequestration. It is suitable even for large scale carbon sequestration projects (Holloway, 2001; Hastik *et al.*, 2015) as an example in the USA state of Texas where this technology has been implemented and consumes about 20 million tonnes of CO₂ (Lackner, 2003). However, in the northern sea, the Norwegian energy company Statoil has sequestered CO₂ removed from natural gas using the underground injection technique (Hinzman *et al.*, 2005; Chadwick *et al.*, 2000; Arts *et al.*, 2007).

Enhancement of Carbon Removal in Biomass

It is a well understood fact that all green plants have the ability to absorb CO₂ during growth and on harvest/utilisation, release CO₂. This is termed carbon cycle and a process culminating from photosynthesis. Biomass for carbon reduction or removal (sequestration) uses the plant crops and their interaction/relationship with carbon cycle to allow the permanent sequestration of elemental carbon within the soil, air and water. It is simply achieved by selecting processes or methods which will ultimately return biomass to the soil while enhancing the conditions for plant carbon or the unstable carbon deposited in the plant/crop to be reduced, returned or restored to its original elemental form and then stored in a stable state. Typical strategies include the implantation of the use of cover crops and some legumes, weeds and grasses to temporarily shield farmlands and crops between planting seasons. Also concentrating grazing livestock in consecutively in days in lesser paddocks within a period, *t*, so the grazing is quite lightly but uniform. This type of activities opens up the soil and creates conditions where plant roots grow deeper and deeper into the soil for better carbon permeation. There are proper soil tilling and mixing due to the fact that animal stocks assist in tilling the soil with their hooves.

There are mastication and grinding of old grasses and deposition of manures into the soil according to FACTBOX (2010). Bare paddocks should be well covered with forages, hays and dead vegetations. These and similar practices will convey technical protection of the soil from the sun which also assist the soil to retain more water and be more poised, attractive and ready for carbon-capturing by microorganisms (FACTBOX, 2010). Restoration of soils of degraded/depleted lands naturally slows down the release of carbon but returns the land to good agricultural and/or other uses. Sequestration of biomass has positive impacts and effects on air, soil and the quality of water generally and there are quite a few good essence and benefits to animals, plants, wildlife, and attendant expansion of food production. It reduces the pollution or the level of contamination from the soil, air, and surface water; also emissions on the land and atmosphere. It is also possible to reverse the overall effects and contributions of soil sequestration. The scenario created can present a situation where the soil is not tilled, rather disrupted or abandonment of agricultural tillage practices, what happens to the soil is that it becomes a net source or harbinger of emissions and greenhouse gases (GHG). The natural situation is that beyond 20–30 years of this type of sequestration (without tillage practices), the soil therefore attains GHG saturation point where it ceases to absorb further carbon.

The carbon fills up soil pore spaces and nothing more. What this entails is that there is a global holding limit/capacity to this type of sequestration, the total amount of carbon that any soil can retain (Sundermeiera *et al.*, 2010), and when this limit is reached, there are consequences. Many possible factors affect the technology and economic costs of carbon sequestration. These include the quality of the soil, transactional costs implications, CO₂ leakages/slippages and probable other unforeseeable damage to the environment. Atmospheric CO₂ reduction is usually a long-term process, therefore the concern for possible immediate turn-over over a long period brings about the reluctance in terms of deployment or in adopting extra expensive techniques/approach to improve the approach. There may be need for a clear-cut techno-economic benefits in terms of breaking even before further investment is anticipated. In countries such as New Zealand and maybe Australia, considerations are rife in for farmers to sell and buy carbon credit emanating from this technologies and good practices already elucidated in sequestering carbon. This is allowed as soon as there are evidences to prove that the farmers have effectively and sufficiently enhanced soil carbon content using the mechanism of sequestration practices (FACTBOX, 2010; Smith *et al.*, 2008; Environmental Co, 2006; Lal, 2004).

Carbon sequestration from biomass or biomass sequestration have demonstrated significant and intensive potential to attain net removal of ambient CO₂ from the environment at technological reduced costs in comparison with the conventional carbon sequestration technologies. There are technical uncertainties however because the development and implementation of large scale biomass sequestration is lean due to lack or little experience and technical know-hows. Demonstration plants of biomass sequestration have not been fully developed; there are still gaps in climate policies to drive implementation. In terms of the economics of production, frameworks for accounting have not been developed. Financial instruments are still missing with vague information on acceptability and public perception on socio-economic impacts and other sustainability issues which are complex and unclear. It is necessary to make conclusion that the deployment of the technologies of biomass carbon capture and sequestration may not be possible in isolation without thoughts on impacts and effects on other inter-related sectors of

climate-energy-food-water nexus. It will no doubt require an integrated approach that will holistically address the complicated links within the nexus and then synergistically harness all together. Average daily CO₂ concentrations continues to plummet geometrically due to anthropogenic activities and industrial consumption of fuels (Sedjo and Sohngen, 2012).

The numerical concentrations are in the neighbourhood of mega and giga parts per million (ppm) of CO₂ from year to year (Hodrien, 2008). If global carbons are increasingly sequestered through expansive enlargements of various proportions of forest plantations of lands on the earth planet, it has been recommended as the most effective and combative measure to mitigate elevated atmospheric concentrations of carbon (IV) oxide, recorded in the *Energy Terms Glossary S* (2010) and in the Glossary of Climate Change. Trapping of CO₂ by forests trees, herbaceous and woody forest products are the major carbon sequestration mechanisms and these materials are natural carbon sinks. An estimation of 50.9% of woody conifers are composed mainly of carbon (Alberta Producers, 2004). Forests and forestry products are considered to proffer the most effective mitigation strategy in reducing and eliminating global warming and its effects (Strack, 2008). The forest ecosystem are carbon pools with traps and storage facilities for more carbon than other terrestrial ecosystems. These have been elaborated in other sections of this chapter. They accumulate long carbon residence time organic compounds inclusive of carbon (Lovett, 2008; McDermott, 2008). To that end, the carbon pool of the forest ecosystem with huge potential have become the focus of the current climate change researchers and scientists (Gorte, 2007).

As forests trees and plants grow, carbon is automatically removed from the atmosphere; they are trapped/stored in the leaves, trunks, branches, wood and soil. It remains stored in the forest ecosystem; but ultimately will be unleashed into the atmosphere once again when these stored materials of the forests are burnt or fully or partially combusted (McPherson *et al.*, 2013) in the form of carbon monoxides (CO) and carbon dioxide (CO₂). As the world's forests covers nearly one-third of the landed space of the earth and also covering up to 80% of the total above-ground terrestrial carbon with almost 40% of the below-ground carbon, therefore playing an extreme critical role in the economy of global carbon cycle (Velasco *et al.*, 2016). Approximations established by the Global Forest Resources Assessment (GFRA) proves that the world's forests can accommodate the storage of over 700 Gtonnes (Gt) of carbon; split into 290 Gt in the biomass which is about 45%; up to 74 Gt in dead woods and litters which is about 12% and finally, about 290 Gt in the soil accounting for almost 45% (Nelson, 1999). The planted areas of forests have presently peaked at 265 million hectares of land which contributes up to 7.5% of the total global forest areas (Poeplau and Axel, 2015). Even though most planted forest areas merely have contributed lesser portions to the total terrestrial carbon equilibrium, their ultimate potential and capacity to absorb, trap and store carbon can be less quantified as it has been acknowledged to play more significant and indispensable roles in the now and future climate change mitigation globally with massive environmental and energy impacts (Goglio *et al.*, 2015).

Processes Used for Biomass Carbon Sequestration

The process transfer and safe confinement or storage of atmospheric CO₂ into other carbon sinks or pools that would have otherwise be emitted or remains in the atmosphere is termed carbon sequestration or sequestration of carbon. The rates of emission of CO₂ from conventional fossil fuels have geometrically increased by over 40% between 1980s and 2000s (Wofsy, 2001) due to increased exploitation, demand, utilisation and expanded industrialisation. The quantities of CO₂ however which have accumulated in the ozone layers of the atmosphere within this same period have remained unaffected, constant and unchanged. The fact is that the excess CO₂ that are being released have only being trapped by other carbon sinks within the ecosystems: the oceans, soils, plants, forests and others. As consequences in this specific situation, sequestration be it naturally induced or anthropogenic, is the only solution led process to curtail this excesses. Anthropogenic carbon sequestration approach will only be aimed at balancing the global carbon account in order to present a future climate safety in addition to anticipated economic growth as a result of this carbon trading. This growth is predicated on neutral carbon strategy of zero gain in the atmospheric carbon sink. This type of approach will require a sequestration of anthropogenically induced CO₂ through safe, environmental friendly and stable techniques with assurance of limited or zero leakage risks and threats (Wofsy, 2001; Lal, 2008). There are numerous processes used for sequestration of atmospheric CO₂ into one of the other sinks also seen as pools. Fig. 2 represents a summary of various processes used for carbon sequestration with technological options for adopting and mitigating atmospheric abundance of CO₂. The choice however of one or more combination of several technologies can be strategic in optimising an acceptable approach as it will better improve the system and also direct actions in developing energy policies for economic growth and climate change mitigation.

Types of Carbon Sequestrations

Sequestration types may be structured into two distinctive categories. They are: abiotic and biotic carbon sequestrations.

Abiotic sequestration

Abiotic carbon sequestration is basically established and confined based on physical and chemical reactions in addition to other engineering techniques and applications without any actual involvement of living organisms whether plants, animals, microbes or

Fig. 2 Summary of various processes used for carbon sequestration with technological options. *Source:* Lal, R., 2008. Sequestration of atmospheric CO₂ in global carbon pools. *Energy and Environmental Science* 1, 86–100.

living organisms. This is according to Lal (2008). The strategy of carbon sequestration by abiotic means in the ocean and in other geological entities or structures elicited considerable research and industrial interests (Freund and Ormerod, 1997) and since then, several development have been unfolding. This is because abiotic sequestration of carbon proves to possess larger and robust sink capacity than its counterpart, the biotic carbon sequestration (Lal, 2008). More interesting and evolving progress has being made in both harnessing, developing and testing the technologies for this type of CO₂ capture; also its transportation and injection modes and processes (Kerr, 2001).

Oceanic injection

Injecting CO₂ streams subterranean into the ocean has been articulated for the last three decades. This method has substantially developed and presents many advantages. However, outgassing can be a weak point. Therefore, a need for stabilization and minimization is necessary.

With regard to stabilization and minimization of outgassing, the injection of CO₂ must be done at subterranean depths. The techniques employed in liquefying separated CO₂ from industrial sources can be achieved using the following techniques:

- injection must be lower than 1000 m from a manifold from the ocean floor and the injected CO₂ being less dense than water will rise to almost 1000 m subterranean forming droplets of fluid dynamic plumes;
- As a more dense CO₂–seawater mixture, the injection is between 500 and 1000 m depth, which sinks the mixture into the deeper ocean floor;
- Discharge can be carried out large pipes and towed behind a ship to drag
- Pumping can be done into a hollow at the bottom of the ocean floor and forma a pool of CO₂ lake.

Finally the liquefied CO₂ that was injected at a subterranean depth of equivalently 3000 m is expected to remain stable as reported by O'Connor *et al.* (2001). The sink capacity of CO₂ sequestrated ocean is approximated at between 5000 and 10,000 Pg C yr⁻¹. This no doubt exceeds the world fossil fuel reserves ever reported (Herzog *et al.*, 1997, 2002). Nonetheless, further research incursions by Auerbach *et al.* (1997), Caulfield *et al.* (1997) and Seibel and Walsh (2001) has it that there are very serious unpleasant effects on sea biota culminating from CO₂ injections. Furtherance to the economics of the technology of CO₂ injection, the question of stability of

oceanic injection should be well explored, investigated and analysed from different perspectives following the ever increasing oceanic stratification and water column in juxtaposition with its adventurous turn over through natural processes.

Geological injection

Generally, the method for geological injection of CO₂ involves the following distinctive approaches: CO₂ capture; CO₂ liquefaction; CO₂ transportation and CO₂ injection into the deep geological strata of the earth. There are also possibilities of injecting CO₂ into old and new coal seams. It is reported that there is possibility of CO₂ injection to be undertaken in coal seams or beds, abandoned oil wells (for yield intensification), saline aquifers and stable rock strata. Researchers like [Klara et al. \(2003\)](#), [Tsang et al. \(2002\)](#), [Baines and Worden \(2004\)](#) and [Gale \(2004\)](#) presented saline aquifers as underground bed layers of very porous sediments filled up with brackish water. Usually, aquifers filled with saline waters are densely positioned underneath the reservoirs of freshwater having layers that are impermeable in between. So industrially produced CO₂ on a large scale can be pumped into the aquifer and hydrodynamically sequestered. In this case, the CO₂ can form carbonates by reacting with other dissolved salts available. Also, supercritical injection mode is used to inject CO₂ having density and viscosity lower than the liquid brine, which it will displace at the spot. In situ sequestration happens when it forms in a gas-like phase and dissolves spasmodically in the aqueous phase, creating a multi-phase cum multi-component condition. It has been reported by [Lal \(2008\)](#) that the injection of CO₂ into reservoirs where oil and gas are displaced could be a potential economic strategy of enhancing oil recovery from the wells. CO₂ can therefore be injected into un-mineable coal beds. In this case, methane as, CH₄ is directly absorbed into the system as studied and presented by [Lal \(2008\)](#). The main concerns regarding geological sequestration of CO₂ are almost similar to oceanic injection earlier presented ([Kintisch, 2007](#); [Schrage, 2007](#)).

The operational and process cost in addition to CO₂ leakages are main issues of concern in geological sequestration. It requires innovative solutions and low-cost approach in order to make this strategy competitive. Low density and low viscosity of injection under supercritical conditions presents daunting challenges; the risks associated with CO₂ leakages and sometimes slippages through confined strata may be too high compared to the currently injected liquid wastes according to [Tsang et al. \(2002\)](#). Furthermore, there is the need to consider chemical interactions of CO₂ in storage with different geological formations; because overtime, this can stimulate other geochemical reactions which may be deleterious and can aid the migration of harmful substances. When articulating strategies for suitable monitoring controls, these facts in addition to impacts must be considered ([Lal, 2008](#)).

Scrubbing and mineral carbonation

Scrubbing and carbonation of mineral carbon is accomplished through the simulation of mimicking of the usual natural inorganic chemical transformation of CO₂. It is a two-way process and the process allows the conversion of industrial CO₂ emissions (from any source) into Na₂CO₃, MgCO₃, K₂CO₃, CaCO₃, and other related minerals ([Fan and Park, 2004](#)). These carbonates being the final products are known to be stable geologically and thermodynamically. This is the aspect of carbon mineralisation. With regards to scrubbing, CO₂ chemical absorption is carried out using an amine or carbonate solvent which is broadly used for carbon capture. Therefore, in this process, scrubbing purifies CO₂ by passing the stream through amine solvent absorption column. Other solvents such as lithium silicate, K₂CO₃ ceramic, absorbent clay, nickel-based compounds are also employed in scrubbing during the absorption phase process. Pure gaseous CO₂ is thereafter recovered by subjecting the CO₂-rich amine to heating and then re-precipitated through mineral carbonation. [Lal \(2008\)](#) reported the successful implementation of carbon scrubbing and mineral carbonation in CO₂ sequestration.

Biotic sequestration

Biotic sequestration focuses on the use micro-organisms and some higher plants (flora) aiming to remove and trap CO₂ from the atmosphere. This option uses the nature ability to remove CO₂ and it is totally different when compared to management options in which there are reductions of emissions or offset of emissions.

Oceanic sequestration

With more than the earth's 70% and its surface, the ocean has a vital prevailing role in the cycling and recycling of global carbon. Also, in climate and its changes, patterns of weather and others. The estimation of 93% of the earth's CO₂ being deposited and stored in vegetation, algae and coral reefs beneath the sea and cycled through the ocean is a reality. Numerous biological processes exist even though more diversified that can lead to the sequestration of carbon in the ocean through photosynthesis. Photosynthetic process by phytoplankton and other such organisms is reported by [Rivkin and Legendre \(2001\)](#) as one of such mechanisms or techniques of oceanic carbon sequestration. It is reported in the ocean floor, some of the phytoplankton's or other organismic particulate organic materials from organisms are dropped and consequently and sequestered. Some metals are necessarily significant in this oceanic processes. It is discovered that the accessibility of Fe is one of the limiting factors on the growth of these organisms, phytoplankton inclusive in the oceanic ecosystems. Hence, quite a substantial number of research have attempted to analyse the significance of fertilization of Iron (Fe) on biotic sequestration of CO₂ in the ocean ecosystem. The studies of [Martin and Fitzwater \(1988\)](#) kick-started the insights, [Falkowski \(1997\)](#), [Martin et al. \(2002\)](#) and [Boyd et al. \(2004\)](#) made several contributions with various perception and variations in results. It was therefore argued and presented that incremental carbon could be trapped and sold as credits using the developing global carbon platform as marketplace. Analogous to this deep injection, [Chisholm et al. \(2001\)](#) in a separate study presented an important fact that ocean fertilization can affect the entirety

of the ecology of the ocean. However, the present situation is that ocean fertilization remains a controversial issue and has affected the way and manner technological incursion towards ocean sequestration are generated (Johnson *et al.*, 2002).

Terrestrial carbon sequestration

The allocation and subsequent transfer of atmospheric CO₂ into biotic carbon sinks is established as terrestrial carbon sequestration. It is reported that about 40%–50% of CO₂ that are anthropogenically emitted are atmospherically stored. This is due to the fact that undetermined terrestrial pools sequester atmospherically stored CO₂ which no doubt plays significant and important roles in the entire carbon cycle globally according to Lal (2008). Our ecosystems that are terrestrial in nature are composed of a major carbon sink directly influenced by photosynthesis which brings about the storage of CO₂ from both living and dead organic matters (flora and fauna). Due to several additional beneficial factors including improved good water quality, soil, air and attendant regeneration of retrogressed ecosystems with increased agricultural yields, terrestrial carbon sequestration has been successively being categorised as a natural strategy of win–win situation by researcher like Lal (2003). Terrestrial sequestration presents numerous advantages in addition to the natural elimination of global climate change incursions and threats. Three main components of terrestrial carbon sequestration are considered in this discourse: They are soils, forest and wetlands terrestrial sequestration based ecosystems. In terms of forest ecosystems, carbons are stored lignin and cellulose. There are also other resistant polymeric carbon compounds relatively present.

It is reported by Wofsy (2001) that in the forest ecosystem, forest carbon is sequestered both in woody debris, woody products, wood leaves and branches, trunks, barks and harvestable timber; also encroaching woody plants and grasses on grasslands. Forestry practices like afforestation can be one of the sustainable options available for carbon sequestration in a terrestrial ecosystems as reported by the intergovernmental panel on climate change (IPCC) in 1999s report and also as presented by Fang *et al.* (2001) and Lamb *et al.* (2005) in their research works. Afforestation however on a commercial and industrial scale can significantly affect other sectors like water resources and environment. It is documented that with afforestation, substantial and steady losses were recorded in streams and river flows. Also, Jackson *et al.* (2005) noted that increased soil salinization and acidification as a result of afforestation. It is also reported by Gorham (1991) and Warner *et al.* (1993) that in terms of wetlands ecosystems, the associated soils or histosols create large and extensive pedologic agglomeration estimated at circa 450 Pg. Wetland soils terrestrial sequestration may constitute as much as 200 times more carbon than the associated vegetations according to Milne and Brown (1997) and Garnett *et al.* (2001).

Soil carbon sequestration suggests the process of enhancing the concentration of pools of soil organic carbon and soil inorganic carbon and sequester them as secondary carbonates or compounds through the conversion of land-use and subsequent implementation of recommended best management practices (RMPs) in the pastoral, agricultural and forestry ecosystems with the restoration of retrogressed and extremely distressed soils. Afforestation is among the most practical possibilities of carbon sequestration in all terrestrial ecosystems. The various reports and studies of IPCC (1999), Fang *et al.* (2001) and Lamb *et al.* (2005) confirm this. In practice, almost 350 Mha or more of most tropical forests have been exploited and converted to other land usages. In addition, over 500 Mha of marginal and non-marginal forests have been degraded to extreme varying scales according to successive studies of (Lal, 2005a,b,c). Consequently, the creation of productive, non-invasive but monocultures of plantations of eucalyptus, acacia, pinus, jatropha and others can bring about the enhancement of the terrestrial carbon sinks and pools in these ecosystems. The schematics in Fig. 3 gives a vivid information on biotic sequestration and the linkages with sub- sequestration options in biosphere as highlighted.

Fig. 4 Various processes used for carbon sequestration. From Lal, R., 2008. Sequestration of atmospheric CO₂ in global carbon pools. *Energy and Environmental Science* 1, 86–100.

Table 1 Comparative analysis of biotic and abiotic sequestration

Parameters	Biotic sequestration	Abiotic sequestration
Type of Process	Humidification by Photosynthesis (Natural)	Technological (capture, injection, sequestration)
Capacity of Sink	finite (between 50 and 100 Pg)	Hugely large (in terms of thousands of Pg)
Horizon Time	Immediately: next 25–50 years	Between 10 and 20 years
Cost Implication	Low, none or negative	High
Yield reduction risk of biomass and NPP	Low or insignificant	
Risk of Human health	Insignificant to low in terms of agricultural chemicals	High
Risk (Leakages)	Small or insignificant (ploughing and so on)	Expensive and complex approach/method
Risk (Environmental)	Effect: positive	High
Verification and monitoring	Routine and simple methods	Expensive and complicated methods
Regulatory approach	Pecuniary incentives may be necessary	Policy and essential legislative measures

Comparison summary between biotic and abiotic methods

The following table summarizes the differences between biotic and abiotic methods for carbon sequestration and the comparison of various parameters. This comparison is further expounded in the schematics in Fig. 4. Highlighted are the various sub-processes as presented by Lal (2008) (Table 1).

Algae Carbon Sequestration

Microalgae are known as photosynthetic microorganisms which can be deployed in the mitigation of CO₂ and concurrently produce value-added products such as fuels and pharmaceuticals. This is possible because being photosynthetic in nature attract CO₂ to themselves which are used in energy creation as green plants in the presence of chlorophyll. In this wise, algae strains or species can provide specific advantages with regard to carbon sequestration and are natural. They are known for their fastidious growth rate, their capability to use brackish, saline, ocean or waste waters rather than fresh water, emissions and effluents for production and therefore, there is no reliance or dependence on arable land resources. Their perennial growth allows for the use of important nutrients like nitrogen and phosphorus compounds and other salts. However, carbon in the form of CO₂ is very

Table 2 Species suitable for CO₂ capture of emission from power plants in literature

Genres and Species	Maximum CO ₂ concentration known	Year and citations of study
<i>Cyanidium celdanum</i>	100%	(Seckbach <i>et al.</i> , 1971)
<i>Scenedesmus sp</i>	80%	(Hanagata <i>et al.</i> , 1992)
<i>Chlorococcum littorale</i>	60%	(Kodama <i>et al.</i> , 1993)
<i>Synechococcus elongates</i>	60%	(Miyairi, 1995)
<i>Euglena gracilis</i>	45%	(Nakano <i>et al.</i> , 1996)
<i>Chlorella sp</i>	40%	(Hanagata <i>et al.</i> , 1992)
<i>Eudorine spp.</i>	20%	(Hanagata <i>et al.</i> , 1992)
<i>Dunaliella tertiolecta</i>	15%	(Nagase <i>et al.</i> , 1998)
<i>Nannochloris sp.</i>	15%	(Yoshihara <i>et al.</i> , 1996)
<i>Chlamydomonas sp.</i>	15%	(Miura <i>et al.</i> , 1993)
<i>Tetraselmis sp</i>	14%	(Matsumoto <i>et al.</i> , 1996)

Note: Huntley, M.E., Redalje, D.G., 2007. CO₂ mitigation and renewable oil from photosynthetic microbes: A new appraisal. *Mitigation Adaptation Strategies for Global Change* 12, 573–608.

important and indispensable in increasing biomass production rates and their influence on the lipids production content to certain degrees are unquantifiable. The use of algae can offer higher rates of carbon capture than any terrestrial plants and this can step up and so can avoid the inherent food vs energy competition with food crops and aimed at limited supplies of land and water. Algae can be grown in any wastewater, murky water, pools, systems and can consume carbon while producing more crude bio- oil under certain manipulation such as: after starvation and variations in the light and dark conditions (Bwapwa *et al.*, 2018a,b).

Characteristics of algae-based CO₂ capture

In describing the features or characteristics of algae based on CO₂ capture, it is emphatic to relate that most microalgal culture does not necessarily required high purity of CO₂. The possibility of direct feeding of flue gases containing between 2% and 5% of CO₂ to the photobioreactor is desired and most cases, has an optimal implication for direct capturing and sequestering. This no doubt simplifies the separation of CO₂ significantly from flue gases. In this situation, other products of combustion including Sox, NOx, VOCs can effectively be employed as nutrients for the microalgae and can simplify the scrubbing of flue gas meant for the combustion scheme or system. The culturing or growing of microalgae can yield high-value sustainable and commercial end-products which could take care of all the capital costs and operational expenses of the entire process while also producing energy for the system. Such process products may include: (1) Mineral-based carbon for steady sequestration, and (2) High commercial and sustainable value chemical compounds. Depending on the choice of algae genres and species selected, more or more of these products or their combination can be aimed and produced during the process.

Species of algae suitable for CO₂ capture from emissions

Table 2 presents a summary of various species that have CO₂ tolerance. It is important to specify that there are species of micro-algae that have the capacity to tolerate or withstand higher concentrations of CO₂ than listed the few listed and the researchers who studied them.

Cost challenges affecting algae-based CO₂ capture

It is reported that there are few or non-comprehensive and evidence-based estimates or quantification so far established on cost implications and estimates of CO₂ sequestration of various sources especially from power plants using algae as spin-off. Most operation are still at the research and development scale. Earlier initial estimates lacks integrity in terms of the economics and technology of exploring algae sequestration of CO₂ especially with current mode of cultivation technologies both at open pond level and with the use of photo-bioreactors.

The Technology of Carbon Sequestration

Carbon capture with sequestration (CCS) is a bioenergy technology that has been well reported in recent literatures (Eloka-Eboka and Inambao, 2017; Zhao and Su, 2014; Xie *et al.*, 2014; Velasco *et al.*, 2016; Poeplau and Axel, 2015; Bwapwa *et al.*, 2018a,b). Carbon sequestration can hypothetically be a compared approach adopted in the reduction of emissions of NOx, SOx, volatiles, particulates, VOCs and others. The only difference however is that CO₂ is the target and the quantity of CO₂ that is generated to be sequestered which are usually much more than those of other emissions. It is therefore possible that CO₂ can be economically sequestered, stored and transported as fuels. The pathways to capture carbon for sequestration have three potential source routes. (1) Many industrial processes and operations generate relative quantity of streams concentrated of CO₂ as derivative by-product. With inherent CO₂ capture in the process, there is relatively low cost of technology. (2) Fossil power plants account for the emission of the overall CO₂ emissions globally, the potential and attention for carbon capture is mostly prevalent. The

concentration of CO₂ in this option is low but there is significant quantity to be captured; the cost of capture is quite significant at 3.5%–5% from gas plants and up to 12%–15% from coal fired plants.

Opportunities for CO₂ sequestration are higher in terms of production of hydrogen fuels from carbon-rich feedstocks. Sources may include: coal, natural gas, biofuels and biomass. These account for relatively pure CO₂ by-products with attendant incremental costs of carbon capture being quite low. Produced hydrogen from this technology could be employed in fuel cells of low temperature. Other hydrogen fuel-based technologies are possible, but also there are issues of technological costs in contemplating and implementing research and development for the huge market and in addition to infrastructures for the new products. The large quantity of captured CO₂ have to be utilised commercially. The values are ideal for scaled projection even as large-scale applications may not be unlimited in the time being. Chemical operations and processes utilising CO₂ needs relatively minimal amounts in the neighbourhood of millions of tonnes: even as billions of tonnes are generated directly from the burning (partial and total combustion) of non-renewable fossil fuels. There is also the possibility to capture huge quantities of CO₂ which could be detained and stored in geological formations and in ocean depths and sea bed. Geological basins for CO₂ include: exhausted oil and gas reservoirs, unmined coal seams at various locations worldwide and deep saline formations. Collected together can take up thousands of mega and giga tons of carbon. The know-how and the equipment for injecting CO₂ into the ground has developed and there are an established techniques. The injection of CO₂ is used to enhance oil recovery. Sequestration in deep saline formations is possible by a combining three mechanisms: (1) In situ fluid displacement by CO₂; (2) CO₂ dissolution into the fluids; and (3) reaction of CO₂ with minerals present in the formation in order to form stable, solid compounds which includes: carbonates, sulphates, phosphates and so on.

There is initial displacement domination, later on, dissolution and reaction becomes more prominent over decades and centuries. Sometimes, abandoned coal closures and strata are prospective storage spots or sites. CO₂ will ordinarily diffuse through the outlets of pore orifice of coals and thereafter are physically adsorbed. The process is analogous to the manner by which adsorption naturally takes place using activated carbon to remove impurities from substances, air or water. CO₂ can be further employed in the enhancement of the recovery of methane in coal beds which can be quite cost-effective as the additional removal of methane from the system can eliminate the operational costs of CO₂ accumulation and storage. The ocean no doubt is the largest potential anthropogenic CO₂ sink. It encompasses an estimate of over 40,000 billion metric tonnes of carbon. While the atmosphere harbours only 750 billion metric tonnes. The terrestrial biosphere has 2200 billion metric tonnes. Extrapolating a timeline of about 1000 years; more than 80% of the current anthropogenic CO₂ emission will be conveyed into the ocean water body. But if the anthropogenic CO₂ is directly evacuated into the ocean, it would facilitate the continuing but slow natural process of sequestration and in turn, will decrease the peak concentration of atmospheric CO₂ and the rate of build-up will be eliminated.

Conclusion

Production of energy generally and subsequent utilisation are the major drivers and contributors of the overall greenhouse gas emissions globally. Biomass carbon sequestration is an interesting technology and a pertinent approach in recovering resources from greenhouse emissions and converting them to useful energy products while at the same time mitigating climate change effects and challenges. It is a strategy towards overall emission reduction and climate change mitigation in the present and future energy dynamic systems, environment and economy. Atmospheric unleashing of greenhouse gases as a result of unprecedented anthropogenic activities is a huge contributor to the ravishing effects of climate change in the global world to date. Every indication allays the fear that with continuous unabated growth in greenhouse emissions, there is a decimal certainty that the impact will lead to accelerated dramatic unimaginable consequences in the earth's planet's climatic, bio and eco-systems. The strategy for mitigation needs to change and potentially urgent too. It has therefore become the focus of many R and D activities giving rise to biomass carbon sequestration. The significance of this reduction and mitigation cannot be over-emphasised as the global world is heading towards a net neutral carbon environment free from pollution and challenging effects of climate change. With many processes being developed to deal with the challenges, effects and issues associated with global warming and overall climate change, biomass carbon sequestration is the most sustainable, significant and acceptable approach and it employs natural and engineered techniques such as biotic and abiotic options while producing more energy which are clean and environmentally acceptable. These options have exhibited huge potentials but require more improvement and development in order to establish low cost investment and sustainable route in the current world. More studies are needed in the future to diversify this technology beyond the use of biomass feedstocks to other renewable energy resources and thereby establishing sustainable methods to eradicate systematically the effect of global warming and climate change in addition to more energy production for the growing world population. Thus the development and deployment of global carbon market can be kick-started with biomass sequestration.

Introduction

The emissions of greenhouse gas (GHG) has noticed a steadfast upsurge since the outset of industrial revolution with an annual increase over the last decade reported to be by an average of 2.7% (Cuellar-Franca and Azapagic, 2015). In order to avert catastrophic aftermath, two major global gatherings took place in Kyoto (1997) and the other one in Paris (2015). The scientific suggestion that came from the two meetings was that average global temperature increase as a result of climate change should be limited to no more than 2°C (Voll *et al.*, 2012). For this target to be achieved, worldwide GHG emissions must be reduced by at least 50% of their current values by 2050 according to IPCC (2013). Carbon dioxide (CO₂) is the most popular and well-known among various other gases that act as GHGs. It is characterized by high anthropogenic emission which acts as one of the major contribution factor to global warming, caused mainly by fossil fuel combustion (Ustadi *et al.*, 2017). The harmful nature and impact of climate change and of fossil fuels are well established (McDonagh *et al.*, 2019).

From pre-industrial level to present, concentration of CO₂ was reported to have increased from 280 parts per million by volume (ppmv) to 395 ppmv and it is estimated to reach a level of 570 ppmv by the end of this century (Goel *et al.*, 2015). The current atmospheric concentration of CO₂ is estimated to be about 750 Giga tonnes which was projected to be on the increase for the next 100 years to come (Fig. 1). This in turn caused the ocean to become acidic and more dangerously creating an imbalance in the manner by which solar ultra-violet rays are trapped in the atmosphere thereby influencing how water is utilized by plants. Upsurge in global temperature is therefore directly related to continuous CO₂ emission (Fig. 2). Another issue considered by environmental agencies that need to be drastically addressed is anthropogenic climate change (IPCC, 2005). Carbon capture and storage is one of the many options that are gaining interest. It is a technology with the prospect of abating the anthropogenic emissions of CO₂ emissions and to achieve the target of holding the increase in the global average temperature at or below the critical 2°C threshold (Thomas *et al.*, 2016; Wang and Qie, 2018). CCS from fossil-fired and bioenergy-fired plants was reported by IPCC (2014) mutually contribute in reducing CO₂ emissions by up to 25% till the year 2100 (Pachauri *et al.*, 2014). Decoupling energy use as well as CO₂ release is a very vital long-term way of halting greenhouse gas emissions with the assumption that energy use will continue to grow (Herzog, 2001). This can be achieved by utilizing renewable energy sources such as hydro, nuclear, wind, solar, geothermal and tidal energy. However, these sources cannot fully replace fossil fuels, particularly given the numerous ways in which such fuels are used and the current global framework for energy. The consequence is that fossil-fuel-based energy infrastructure is currently been planned that will remain for decades, continuing to increase atmospheric CO₂ concentration. This article reports an overview of the CCS technology, its relevance as a multi-functional climate change mitigation option for oil and gas companies and the associated challenges of its implementation.

Despite the controversy in the effects of carbon dioxide in the atmosphere, the average temperature of the Earth is rising, especially when measured at the poles. Fig. 2 show good correlation between the average Earth surface temperature correlates with the amount of CO₂ in the atmosphere (i.e., upsurge in the atmospheric CO₂ levels is directly proportional to the increase in surface temperature).

Overview of the CCS Technology

Carbon capture and storage (CCS) is a technology that involved disengagement of CO₂ from industrial and energy related sources (large stationary sources), transport to a permanent storage location and complete isolation from the atmosphere (FAO, 2009). This implies that CO₂ must first be isolated from the emission point(s), emanating from the burning of fossil fuels before being stored permanently in a manner that prevents it from entering the atmosphere. Addressing the sequestration of CO₂ from widely distributed and/or mobile emission sources such as residential heating, automobiles and airplanes, is currently impractical but necessary (Williams, 2006). The process involved three important stages as described below.

Stage 1: Capture process

Before capturing CO₂, separating it from other flue gases that results from combustion and/or other industrial processes must first be achieved. This could be done by post-combustion, pre-combustion or oxy-combustion method or oxyfuel capture (Markewitz *et al.*, 2012).

The post-combustion process (gas scrubbing or flue gas method) involved scrubbing the gas exiting the combustion or production process (Heafeli *et al.*, 2004). The capture process is practised at over a dozen plants all over the world, which is based on chemical absorption. Up to 99% of the gas exiting a boiler or a gas sweetening unit can be captured. Mono ethanolamine (MEA) is the most popular solvent usually employed with the process described in the following equations (Galadima and Garba, 2008).

- (1) $2\text{RNH}_2 + \text{CO}_2 + \text{H}_2\text{O} \rightarrow (\text{RNH}_3)_2\text{CO}_3$
- (2) $(\text{RNH}_3)_2\text{CO}_3 + \text{H}_2\text{O} + \text{CO}_2 \rightarrow 2\text{RNH}_3\text{HCO}_3$

Fig. 1 Global CO₂ emissions. Source: <http://courses.knox.edu/envs101/tempco2.JPG>.

Fig. 2 Effect of CO₂ emissions on global temperature. Source: <http://courses.knox.edu/envs101/tempco2.JPG>.

- (3) $2\text{RNH}_3\text{HCO}_3 \rightarrow 2\text{RNH}_2 + 2\text{H}_2\text{O} + 2\text{CO}_2$ [Amines regeneration and carbon dioxide release for transportation to appropriate geological storage unit]. Alternatively, the process can obey the following mechanism

$\text{R} = \text{C}_2\text{H}_4\text{OH}$ when the employed solvent is MEA.

To date, the chemical absorption processes with monoethanolamine (MEA)-based solvents is being used by all commercial post-combustion CO₂ capture plants. MEA was developed over 70 years ago as a general, non-selective solvent to remove acid gases, such as CO₂ and hydrogen sulfide, from natural gas streams. The process was modified to incorporate inhibitors that reduce solvent degradation and equipment corrosion when applied to CO₂ capture from flue gas. Concerns about degradation and corrosion also kept the solvent strength relatively low (typically 20%–30% amines by weight in water), resulting in relatively large equipment sizes and solvent regeneration costs (Chavez and Guadarrama, 2008).

Fig. 3 Flow sheet diagram for post-combustion capture. Source: Chavez, R., Guadarrama, J.J., 2008. Optimized process for post-combustion CO₂ capture in thermoelectric power plant using structured packing. Available at: <http://www.aidic.it/pres11/webpapers/291Chavez.pdf>.

The flow diagram of the main process is depicted in Fig. 3. Gas flow G1 gets entry from the bottom of the absorption column with the liquid flow L1 coming in from the top. The rich liquid amine stream L2 enters to a heat exchanger to raise its temperature and then pass to the stripper where it carries out amine regeneration. For the sake of verifying the mass balance of the whole process, the regenerated liquid flow is mixed with MEA solution at 30% weight L5. Stream L6 is re-circulated to the absorption column. The stability of the stream L5 was due to know the iteration number in the simulator (Chavez and Guadarrama, 2008).

Post-combustion capture has an edge over other capture technologies, having the advantage of being compatible with existing coal-fired power plant infrastructure as well as being retrofitted without requiring tangible change in basic combustion technology. It has the highest priority when it comes to gas-fired power plants. Neither the oxy-combustion nor the pre-combustion approaches are well suited for gas plants.

Another advantage it offers is flexibility as the power plant can still operate even if the capture plant is off but the other two capture options are highly integrated with the power plant: So if capture fails, the entire plant must shut down. It also proffers utilities which allow for increased capacity by temporarily restraining the capture process during periods of peak power demand.

Pre-combustion/syngas method is appropriate to integrated coal gasification combined cycle (ICGCC) plants, where by synthetic H₂ and CO₂ rich gas is produced from the fuel (Heafeli et al., 2004). It first involved the gasification of coal to generate the synthetic gas comprising of CO and H₂ followed by “water-gas shift reaction” of the CO to produce CO₂ for capture and H₂ to a turbine to generate electricity. This clean coal technology has good potential for future generation and is currently practised in few existing facilities in the US and Europe.

Oxy-combustion process involves burning the fossil fuel in pure or enriched oxygen to produce a flue gas consisting mostly of CO₂ and H₂O vapour. The CO₂ can be piped directly to storage unit after being compressed. Cooled flue gases are circulated with the sole purpose of limiting the resulting flame temperatures to levels common during typical combustion and injected into the combustion chamber. The constituents of flue gas are mainly carbon dioxide and water vapour, the latter of which is condensed through cooling. The result is an almost pure carbon dioxide stream that can be transported to the sequestration site and stored. Power plant processes that relies on oxyfuel combustion are also referred to as “zero emission” cycles, because the CO₂ stored is not a fraction removed from the flue gas stream (as in the cases of pre- and post-combustion capture) but the flue gas stream itself. It is also worth noting that no matter how small a fraction of CO₂ generated during combustion, it will inevitably end up in the condensed water. Thus the water would have to be treated or be disposed fittingly to merit the label “zero emission”. The technique is encouraging though the initial air separation step demands a lot of energy. This process is still at the Research and Development (R & D) phase. The main stages of the above-mentioned three carbon capture methods are summarized in Fig. 4 (Agrali et al., 2018).

Chemical looping combustion (CLC) is an alternate method though under development. It is a method based on utilization of a metal oxide as solid oxygen carrier. Metal oxide particles usually produces solid metal particles with a mixture of carbon dioxide and water vapour when reacted with solid, liquid or gaseous fuel in a fluidized bed combustor, condensing the water vapour thereby leaving the pure carbon dioxide ready for sequestration. The solid metal particles are circulated to another fluidized bed where they react with air, producing heat and regenerating metal oxide particles that are recirculated to the fluidized bed combustor.

Eradicating CO₂ from the atmosphere is a form of geoengineering by greenhouse gas remediation. Widespread media coverage was given to techniques of this type due to their upper hand in offering the promise of a comprehensive solution to global warming if they can be coupled with efficient carbon sequestration technologies. It is more common for such techniques to be proposed for air capture, than for flue gas treatment. Carbon dioxide capture and storage (CCS) is more commonly proposed on plants burning coal in oxygen extracted from the air, which means the CO₂ is highly concentrated and no scrubbing process is necessary. A hierarchical and multiscale framework was presented by Hasan et al. (2015) to design CCS and CCU supply chain networks with less investment, operating and material costs by taking into consideration the selection of source plants, capture processes, capture materials, CO₂ pipelines, locations of utilization (for enhanced oil recovery) and sequestration sites, and

Fig. 4 Basic principles of carbon capture. Reproduced from Agralı, S., Üçtug, F.G., Türkmen, B.A., 2018. An optimization model for carbon capture & storage/utilization vs. carbon trading: A case study of fossil-fired power plants in Turkey. *J. Environ. Manag.* 215, 305–315.

amounts of CO₂ storage. A profit of \$9.23 per ton of CO₂ was achieved by their optimized network. An optimal solution to the problem of choosing between CCS and carbon trading was founded by Üçtug *et al.* (2014) for a hypothetical methanol production facility. A non-linear optimization approach was employed with the objective of maximizing the net returns from pursuing an optimal mix of CCS and carbon trading. The results are sensitive to carbon credit prices and the discount rate, which determines the choices with respect to the future and present. Three alternative CCS configurations to the benchmark process which is absorption by using monoethanolamine, (MEA) as solvent was compared by Schach *et al.* (2010). They concluded that “the process with the highest energy savings is not the lowest cost of CO₂-avoided, and the influence of rising investment costs of more complex configurations cannot be ignored.” A coal-fired power plant was also studied by Cristobal *et al.* (2012a) for which they considered installing four control devices in series. They assumed that bypassing one or more of these devices before the CO₂ discharge point would be possible. They develop a mixed-integer nonlinear programming (MINLP) model that determines which devices to use and the operating condition of each device. MINLP was also developed by Cristobal *et al.* (2012b) for a similar problem where a set of pollution control retrofitting alternatives are considered to be installed in a cap and trade framework.

Stage 2: Transportation process

I was reported by IPCC (2005) that the gas should be transported safely except in the situation when emission point is located directly over the storage unit. Onshore pipelines have been utilized since the 1970s in the USA. About 5800 km of CO₂ pipelines were reported in the United States in 2008, with most of them in the Permian Basin of Texas. CO₂ is being transported to oil production fields by these pipelines where the CO₂ is injected in older low producing fields to enhance oil recovery by EOR. Another option for the gas transportation is by liquidification like liquidified petroleum gas (LPG) and transported through ships or ocean going tankers. In the case of small scale applications, rail cars may also be employed. CO₂-transportation generally depends on distance, quantity and cost.

Stage 3: Storage process

Large quantities of captured CO₂ could be stored in different geological formations, minerals and deep oceans as believed by scientists and engineers.

Ocean storage

Oceans can accommodate CO₂ due to its being appreciably soluble in water. Upon its capture, CO₂ could potentially be injected directly into deep oceans and most of it would remain there for millions of years (IPCC, 2005). It was reported by Herzog (2001) that the ocean embodies the largest storage option for the gas. Already 40,000 Giga tonnes of CO₂ were reported to be confined in the oceans in relation to the atmospheric concentration of only 750 Giga tonnes. Thus, quantities of CO₂ that would double its atmospheric concentration would only change the ocean’s concentration by 2% (Herzog, 2001). As such the countries with better chance of storing large volume of the gas are those that are closed to the oceans. Below are among the various concepts proposed for the ocean storage:

- Injecting CO₂ by ship or pipeline into the water column at depths of 1000 m or more, and the CO₂ subsequently dissolves.
- Depositing CO₂ directly onto the sea floor at depths greater than 3000 m, where CO₂ is denser than water and is expected to form a 'lake' that would delay dissolution of CO₂ into the environment.
- Converting the CO₂ to biocarbonates (using limestone).
- Storing the CO₂ in solid clathrate hydrate already existing on the ocean floor, or growing more solid clathrate.

Negative environmental effects of oceanic storage are usually reported though poorly understood. Living organisms in the ocean are usually killed by high concentration of CO₂ and also the ocean storage is not permanent too as the dissolved CO₂ would eventually equilibrate with the atmosphere. Also, the CO₂ reacts with the water to form carbonic acid, H₂CO₃, hence increasing the acidity of the ocean water.

About 1600 years was the order of time estimated to take water in the deeper oceans to circulate to the surface. The retention of CO₂ in the ocean would be enhanced by the bicarbonate approach which reduce the pH effects, but other environmental effects and cost will also increase.

The inevitability of the effects of making the ocean more acidic are absolute as illustrated by Fig. 5, which are easy to predict due to reliance on simple chemistry, not on complex computer models of climate. The ocean already holds 400 Billion tons of fossil fuel CO₂. Consequently, the ocean is already 0.1 pH units more acid than before industrial CO₂ emissions. This means nutrients for plankton in the North Sea, and all shallow ocean waters, are changing rapidly. This is the base of the food chain for invertebrates, shells and, eventually, economic fishing. By 2050 the ocean will be five times more acid than at any time since glaciation (change pH 8.4 to pH 7.8).

Mineral storage

Another form of carbon sequestration involve the reaction of naturally occurring Mg and Ca containing minerals with CO₂ to produce carbonates as can be seen from the following reactions.

In this process, stable carbonates are produced by exothermically reacting CO₂ with abundantly available metal oxides. This is a process that occurs naturally over many years and is responsible for much of the surface limestone. Reaction at higher temperatures and pressures or pre-treatment of the minerals made the reaction rate to be faster although the method may require additional energy. The IPCC estimates that a power plant equipped with CCS using mineral storage will need 60%–180% more energy than a power plant without CCS.

Geological storage

Several factors such as geological setting, integrity of the hydrocarbon column height (cap rock), quality of the reservoir and possibility of unexpected events like earthquake need to be considered in order to strike a balance between permanent storage and risks of leakage with regards to the geological storage options. Geological storage options involve depleted oil and gas reservoirs, offshore and onshore deep saline formations, use of CO₂ in enhanced hydrocarbon (oil or gas) recovery and in enhanced coal bed methane recovery (Galadima and Garba, 2008). In 2001 according to Herzog and Golomb (2005), about 200 million cubic

Fig. 6 Application of CCS for EOR and enhanced methane recovery from coal seams.

meters of the gas were believed to be injected into more than 30 different oil and gas fields of Alberta and Columbia. The gas could also be utilized in improving the recovery of coal bed methane especially with the fact that the surface structure of coal has good adsorption affinity for CO_2 . With the possibility of achieving return on investment in short time, EOR becomes an economic option with special interest to many oil and gas companies leading to the availability of more than 80 CO_2 -EOR projects worldwide in the last 9 years, producing 200,772 bbls of oil per day (Herzog and Golomb, 2005). In general, the cheapest and most environmentally friendly storage option is the geological storage.

Benefits of CCS Technology

Utilization of the gas for enhanced oil recovery (EOR) is one of the major potential benefits of the CCS. The method has the advantage of increasing the oil amount that is recouped from an underground oil reservoir. By pumping CO_2 into an oil reservoir, previously unrecoverable oil is pushed up through ideal displacement to where the oil can be reached (Fig. 5). Additional 30%–60% of the original amount of recoverable oil was reported by the U.S. Department of Energy (DOE) once all the recoverable oil has been reached, and the depleted reservoir can act as a permanent storage site for the CO_2 (MGA, 2009). As reported by Galadima and Garba (2008), CO_2 has been injected into over 11,000 oil wells for tertiary recovery since late 1970s and the technology already accounted for over 15% of annual oil and gas production in the region in the Permian basin of Texas United States.

“Sleipner Project”, is an example of the commercial success of the technology. It is a project where the gas is compressed and pumped into 200 m thick Utsira sandstone layer of the Sleipner oil and gas field in the North Sea United Kingdom (Herzog, 2001). The investment was paid back in about one-and-half years only with about 1 million metric tonnes of CO_2 reported to have been sequestered annually since October 1996 (Herzog, 2001). Another project is called the Weyburn- CO_2 monitoring project, Canada which accounts for about \$30 million of gross revenues to the gasification plant’s cash flow each year (Heafeli *et al.*, 2004). Up to 20 million tonnes of CO_2 would be injected and permanently stored, leading to at least 130 million barrels of additional oil recovery for the project life cycle.

As can be seen in Fig. 6 with regard to oil and gas companies involved in methane exploitation from coal beds, studies reported the possibility of injecting up to 173–203 billion tonnes of the gas for enhanced coal bed methane recovery (ECBMR) world-wide. In a country like Nigeria that is developing, the current proven oil and gas reserves (36.22 bbls & 184 tcf) were projected to last for the next 40 years (Galadima *et al.*, 2009), indicating that future CO_2 -enhanced oil recovery is necessary.

The conversion of CO_2 into hydrocarbons is a potentially useful way of dealing with industrial sources where it can be stored or reused as fuel or to make plastics with quite a number of projects investigating that possibility. Currently, biofuels represent the other potentially carbon neutral jet fuel available. Carbon dioxide scrubbing variants exist based on potassium carbonates which can be used to create liquid fuels. Although the creation of fuel from atmospheric CO_2 is not a geoeengineering technique, nor does it actually function as greenhouse gas remediation, it nevertheless is potentially very useful in the creation of a low carbon economy, as transport fuels, especially aviation fuel, are currently hard to make other than by using fossil fuels. A proven process to produce a hydrocarbon is to make methanol. Methanol is rather easily synthesised from CO_2 and H_2 .

By heating CO_2 up to the temperature of 2400°C , it dissociates into carbon monoxide and oxygen. Another important process that can be used to convert CO into hydrocarbons is the Fischer-Tropsch process. The required temperature can be achieved by using a chamber containing a mirror which focuses sunlight on the gas.

In addition to all these, the captured CO₂ can be applied for various other household and industrial applications which include production of carbonated drinks and soda water, electric fire extinguishers, polymers and plastics, industrial welding urea or as a promising solvent for organochlorine in the removal of caffeine from coffee, lipophilic organic compounds as well as an industrial gas laser (CO₂-laser). These therefore give a chance to various oil and gas companies to diversify their investments by establishing related industries

Implementation Limitations and Challenges

It was claimed that even very low leakage rates could undermine any climate mitigation effect, for that safe and permanent storage of CO₂ cannot be guaranteed. However, some geologists argued that the proportion of CO₂ retained in appropriately selected and managed geological reservoirs is likely to exceed 99% over 1000 years. There is major concern here with CCS as to whether the leakage of stored CO₂ may compromise the technology as a climate change mitigation option. For well-selected, designed and managed geological storage sites, IPCC estimates that risks are comparable to those associated with current hydrocarbon activities. For ocean storage, its depth is very crucial in determining the CO₂ retention. It was estimated by IPCC that 30%–85% would be retained after 500 years for depths of 1000–3000 m. With regard to mineral storage on other hand, it is free from any risks of leakage.

The degree of challenges for CCS implementation can be viewed from country perspective. Majority of developing countries cannot successfully adopt the CCS technology in the short term despite certain progress being achieved in terms of its life cycle assessment. Several factors covering technology to regulatory policies could be attributed to this fact.

Technology

Shifting towards low-carbon energy sources (more importantly biofuels) has special interest in many countries; most projections show that the current environmentally undesirable fossil fuels will in the medium term continue to play a crucial role. For example coal demand alone in developing countries will likely increase from 4215 to 5647 million tonnes from 2015 to 2030. In ensuring the successful capture of CO₂ that will be emitted in line with the combustion of these fuels, an effective technology is very vital. For successful “Clean Coal Technology” alone, a range of modern technologies that are currently not available in developing countries are certainly required. These technologies will cover the preparation of coal (washing and briquetting), combustion for example by fluidised bed boilers and gasification, and clean-up of undesirable gases by processes like flue gas desulphurisation and denitrification before the ultimate carbon capture and storage. In fact the whole CCS process involved series of advance technologies, few of which are under early stages of practise in some industrialised countries like United Kingdom and U.S.A. This clearly indicates that inefficient technology will lead to a serious setback in implementing CCS in many regions and most developing countries, who do not have enough technology to provide their citizens with basic amenities (Galadima and Garba, 2008).

Capture and storage cost

The country, technology and fuel types have a big influence on the costs of capture, transport and storage of CO₂. For example, the cost of capture from gas-fired power plants will be lower than from coal power plants due to lower concentration of the gas. Similarly transportation cost varies with applicable options with ships and pipelines emerging as the most viable transport options in many regions. Different authors reported varying cost estimates. In an analysis by Anderson and Newell (2003), they estimated storage costs of \$7 to \$19 per 1000 Kg of CO₂ total transport while Hendriks *et al.* (2000) reported \$13 to \$44 per 1000 Kg of the gas (Galadima and Garba, 2008). The transportation distance of 1000 km was assumed by both authors, implying an upsurge in both transportation cost and risk of corrosion for longer distance (especially for offshore pipelines). In a developing country like Nigeria for example, the costs are much likely to be higher due to metocean conditions, requiring advance pipelines technology and potentially longer transportation distance. This may have an earnest effect in its implementation except otherwise if forced by government or oil and gas companies make use of the gas in enhanced oil recovery (EOR). The consequence will rise in oil and gas consumers cost and when this is connected with the current poverty situation, the masses would be at serious disadvantages (Galadima and Garba, 2008).

Capture and storage policies

For the successful implementation of CCS, the right approach must be developed by the major emitters (oil and gas companies) and other companies permitted by the government to be involved in power distributions and related services as well as other industry participants that integrates important solutions and previous lessons from international sectors like the natural gas company of America. This should include development of government regulatory frame works that ensure unconditional commitment and national support. Putting into consideration the existing environmental policies in many countries that do not address this issue, its implementation will be stuck along the way if the government do not either introduce a new regulatory frame work that encourages its development or modify the current regulations to ensure that capture and storage responsibilities are assigned to the actual emitters. In essence, the oil companies should initiate CCS in addition to the biofuels options based on the current environmental policy (Galadima and Garba, 2008).

Implementation time

Sufficient time and planning is also very crucial when it comes to the implementation of CCS system that can capture desired quantities of greenhouse gases. In order to promote the efficient isolation and capture of CO₂, Each oil and/or gas formation as

well as power generation facility (medium or large) requires unique method innovations (Galadima and Garba, 2008). There is the need for appropriate technology and equipments to be put in place for the transportation of the gas either by pipelines or ships and also the number of capture facilities fully implemented upon the effective capture costs and cost-sharing agreement finalised between companies and appropriate authorities assigned by the government. Other reasons that can lead to the shift of project to a longer period in many countries in addition to lack of efficient technology suitable for CCS include poor planning and implementation policies, potential cost inconsistencies, serious corruption problems and unmitigated insecurity in the oil industry. Early compliance by oil and gas companies being the major emitters is another indicator of how shortly and successfully the implementation will be. However, for CCS project to be successfully executed in the short term, those problems need to be adequately addressed, which will yield positive results though very difficult (Galadima and Garba, 2008).

Conclusion

Carbon Capture and Storage (CCS) is a carbon emissions reduction process receiving special attention globally today. The technology provides a good solution against the global climate change. It also provide low-carbon approach to use non-renewable fuels like coal or natural gas to ensure security of power supply and is a good opportunity for Enhanced Oil Recovery (EOR) from low producing or partly depleted petroleum formations. In this article, an evaluation of CO₂ capture, transportation and storage potential was given, which include storage site screening, storage mechanism analysis, and storage capacity evaluations. Though the current economic situation does not consider the process as financially viable, CCS will play a significant role in mitigating future emissions especially from developing countries. However, careful approach is required to avoid more problems than benefits. Successful implementation of the technology must be planned ahead of time, effective future agreement is required from the sides of both government and oil companies, policies and strategies shall be base on research findings by environmental, geological and policy analysts couple with lessons from prior developed and developing countries. With correct policies, government and financial support, CCS will undoubtedly play more and more important role on sustainable development.

Carbon Footprint Reduction Instrument

Sk M Haque, University of Calcutta, Kolkata, India

Introduction

Carbon foot printing is the process of quantifying the land segment of carbon gas emission interconnected with human activity. Usually, the carbon footprint is related to the production of a product, the delivery of a service or, more generally, the occurrence of some process. The term 'carbon footprint' is commonly used to portray the land unit based on the total amount of CO₂ along with other GHG emissions for which different type of land use is responsible. Thus, carbon footprint has become extensively used term and concept in the public debate on responsibility and abatement action against the threat of global climate change. Over the last few years, a tremendous increase in public appearances across the media, the government and the business world have been seen a wide range of awareness towards it. However, it is difficult to understand what exactly 'carbon footprint' is to the common? Despite its ubiquitous appearance there seems to be no clear definition of this term and there is still some confusion what it actually means and procedures to follow and which unit to be used. While the term itself is originated from 'Ecological Footprint' (Wackernagel and Rees, 1996a,b), the general idea is related to the carbon footprint of some land segment responsible for gaseous emissions, that are also relevant to climate change in connection with production or consumption activities of human society. However, this is almost where the commonality ends. There is no consensus on how to calculate a carbon footprint. The spectrum of definitions ranges from direct CO₂ emissions to full life-cycle GHG emissions and not even the units of measurement are clear. The change in on earth surface which is as a result of anthropogenic activity since the start of the industrial revolution. Scientific evidence proved that the burning of fossil fuels contributes to raising the average temperatures and extreme weather events (Rosenzweig *et al.*, 2001; Mitchell *et al.*, 2006; Solomon *et al.*, 2007).

Carbon footprint or amount of CO₂ emission allied with all the activities of human or other things (e.g., person, building, corporation, land segment, country, etc.) which contain to direct emission results from fossil-fuel combustion in manufacturing system, heating and transportation, as well as emissions required to produce the electricity connected with goods and services consumed. It includes the emissions of other greenhouse gases like methane, nitrous oxide or chlorofluorocarbons (CFCs). Canadian ecologist, William Rees and Swiss-born regional planner Mathis Wackernagel have invented the ecological footprint from which the concept of carbon footprint has been taken out in the early 1990s at the University of British Columbia. An ecological footprint is the total area of land required to maintain an activity or population which comprises environmental impacts, such as water use and the amount of land used for food production. In contrast, a carbon footprint is usually expressed as a measure of weight, as in tons of CO₂ or CO₂ equivalent per year. The carbon footprint of a person, organization or object can be accessed on the basis of the emission of carbon components such as CO₂. In other words, the carbon footprint is the total amount of land responsible for CO₂ and other GHG generation through the life cycle of any product or service. Although the different forms of footprint counting are established in the domain of ecological and environment science, land-use and land-cover controlled assessment of carbon footprint is found in gaps. A person's carbon footprint is calculated in terms of major categories of consumption like housing, travel, food products, and services etc. All these components are directly linked with the land use and land cover (LULC) practices of the urban environment which include various parameters of energy utilization like fuel use, calorie consumption, travel expenditure, distance, and spending behavior. The suitable emission factor takes into account the relevant life cycle as much as possible. In a year, a city-dweller emits 4 ton of carbon dioxide.

Carbon footprint examines the climate change impact of each activity ranging from making a product, living a lifestyle. Generally, a carbon footprint considers not just the CO₂ emission of a particular activity but also escaping of all other GHGs such as methane and nitrous oxide. On the contrary, biomass on the terrestrial systems has the greater potentiality to absorb carbon component that also plays an important role in balancing anthropogenic carbon emissions (Pacala *et al.*, 2001; Pan *et al.*, 2011). Indeed, carbon sink or storage capacity varies between different terrestrial ecosystems, geological formation, and oceanic deposition; on the other hand, changes in land utilization categories from high-vegetated to low-vegetated biomass usually, result in the high amount of carbon emissions into the atmosphere. This type of land-use changes in an urban area not only increases the atmospheric carbon through vegetation biomass directly, but also lowers the amount of vegetation residues returned to the topsoil as an organic matter, which turns to soil humus, by the process of mineralization. This subsystem is the main source of carbon storage as a soil organic carbon (SOC) (Post and Kwon, 2000). Unlike the directly release of Carbon dioxide from fossil fuel into the atmosphere, pests and diseases help to avoid carbon emissions from dead plants; proper fertilization and drainage can also promote vegetation growth, which may increase the accumulation of SOC (Michal and Price, 1996). Thus, globally the LULC changes have a major impact on the extent and distribution of terrestrial carbon emissions (Shevliakova *et al.*, 2009; Van der Werf *et al.*, 2010). It is expected that LULC change has contributed about one-third of all anthropogenic carbon emissions since the industrial revolution (Houghton *et al.*, 1999) and it has a share of 12.5% of total emissions between 2000 and 2009 (Friedlingstein *et al.*, 2010). As a result, the impact of changes within terrestrial ecosystems on carbon balance has been a focus of land dynamics research in recent decades (Houghton *et al.*, 1999; Houghton *et al.*, 2000). Several studies have been investigated the disturbance of carbon pools by human activities using bookkeeping models, which track the changes in areas of different land

utilization types and also used standard growth and decomposition curves to calculate the change in carbon pools (Houghton *et al.*, 1999; Dixon *et al.*, 1994). Others have estimated the effects of LULC change using spatial models that internally computed the carbon density in vegetation and soils of different ecosystems based on climate and other factors (Shevliakova *et al.*, 2009). Carbon emissions caused by deforestation, cultivation, and other land-use changes have been widely reported (Gaston *et al.*, 1998; Delcourt *et al.*, 2001; Houghton, 2003). Compared to biomass carbon pools, soil organic carbon stocks have been shown to undergo much larger changes due to the dynamism of LULC (Pan *et al.*, 2004; Huang and Sun, 2006).

Urban areas have been recorded 76% of CO₂ emissions owing to energy used and shared about 43% of global primary energy-related CO₂ emissions (O'Meara, 1999). In this background, the aim of this article is to understand the ways of reduction of household emissions of CO₂ in Kolkata and its determinants to mitigate CO₂ emissions through appropriate land utilization practices. In this connection, the estimation of LULC based carbon footprint has been emphasized and the study of its temporal changes has been incorporated through the various components of the Geographic Information System (GIS) platform. Detailed ward level data on LULC (as secondary information) and household categories (as primary and empirical information) have been used for understanding the nature of footprint. Know how regarding the household emission patterns in Indian city matters for several reasons. First, urbanization is likely to become the most relevant land transformation process in India for structuring future emission. Hence, it becomes increasingly important to study the specific role of growing cities in shaping GHG emission profiles. Second, on a more detailed level, recent studies have highlighted the aggregated or segmented direction of energy use and GHGs emission of cities but these all are insufficiently examined the household level data (Dhakal, 2009; Marcotullio *et al.*, 2011; Creutzig *et al.*, 2012; Makido *et al.*, 2012; Chavez and Ramaswami, 2013).

India is the second most urban populous country in the world (after China, with about 760 million) with an urban population of 410 million (32% urbanization level) which is projected to reach 814 million (with a 50% urbanization level) in 2050. The current share of India's urban population to the world urban population is 10.5% which is anticipated to grow to 12.8% by mid-century (UNDESA, 2015). Management of the population distribution across urban centers also matters for climate-change improvement. All footprints have a wide range scope for environmental impact assessment, though this carbon footprint is also computed. Since no process is completely isolated, land boundaries must be set regarding what to include in the carbon footprint. For example, carbon footprint could take into account the acquisition of raw materials and the disposal of the products or purely the manufacturing wastes of the product from the raw materials (Lenzen and Dey, 2000).

Changing Dimensions of Land Utilization and Carbon Footprint

Uncontrolled urbanization in connection with excessive population pressure especially in the developing countries generates the drastic alteration of the land utilization practices within the urban area and its immediate surroundings or periphery. Although the alteration process of land use from one type to another is found primarily at the regional or local level, with temporal changes at the local level, various criteria play an important role on the local environment (Ramadan *et al.*, 2004). During last several centuries near about 80% of the earth's land surface area has been prone subjected to change (Vitousek *et al.*, 1997; Ramadan *et al.*, 2004; Pabi, 2007) by the both natural as well as anthropogenic drivers. Human-induced land cover and land use changes have been found near 30% of the earth's surface (Robinson, 2011; Houghton, 1994; Vitousek *et al.*, 1997). Huge population growth and excess demand on land resource causes the dramatical alteration of land's nature and converted the land from one use to others (Dlamini, 2011). In the case of Kolkata, the extension of the built-up horizon is excessively high than the other cities located in North-East India (Haque and Bandyopadhyay, 2012). Within the aerial unit of high population concentration in this metropolitan region, the high rate of demand for services, facilities, and resources have been generated. Geographically 'there is an urgent need for accurate and timely land-based information' (Subudhi, 2001) to facilitate better and smart services. For the decision-making purpose in terms of urban land use alteration, GIS-based spatial models act as powerful tools.

Modern remote sensing technology has already been shown the capability to detect and analyze the LULC changes particularly in the mega-city regions (Kumar *et al.*, 2011; Welch *et al.*, 1998; Harris and Ventura, 1995; Westmoreland and Stow, 1992; Ehlers *et al.*, 1990). Initially, both the term 'Land Use and Land Cover' are closely linked and interchangeable (Anderson *et al.*, 1976). Today, the term 'Land Cover' is being used in association with the term 'Land Use'. But from the geospatial viewpoint 'Land Use' differs from the 'Land Cover' and there are some differences between these two. Almeida (2005) stated that in the domain of spatial science 'there are various definitions to define these terms like land, land use and land use changes; and they vary according to the purpose of application and to the context of their use'.

From the viewpoint of natural science Wolman (1987) and Stewart (1968) made some arguments that the term 'land' is being used in a collective sense because it is considered as a natural, non-renewal and green resource. The extensions of these natural resources are found around the earth surfaces, including 'climate, landform, soil, vegetation, fauna and water' (Almeida, 2005). However, considering only the natural limits may not give sufficient results regarding the concept of 'land'. Therefore, Hoover and Giarratani (1984) considered three different views from the economical side of the 'Land' stated that it is a 'first and foremost denoted space' which integrates 'topographic, structural, agricultural, and mineral properties of the sites', and includes 'the climate, the availability of clean air, water, and immediate environmental characteristics'.

Jones and Clark (1997) and Lambin and Geist (2004) illustrated that there are two different ways to change the land use practices, firstly direct conversion of one type to another type of land use, secondly simultaneous modification of present land use practice (Almeida, 2005). The processes of land use alteration have characterized by the functional as well as structural

complexities. The nature, magnitude, spatial extent and impact of human alteration of the land utilization system have been considered as an unpredictable fact in modern times. In this connection, quantitative and spatially explicit data is more vital in the scientific community for the understanding and systematic analysis of land use related carbon generation and absorption process. 'The modern world is rich in geographic information' (Dekker, 2005), so the spatial dynamics of land utilization facts is being emphasized with the trend of rapid changes regarding the above-mentioned theme. Computer-based modern spatial science techniques provide cost-effective multi-spectral and multi-temporal data for better management, understanding and monitoring the land carbon generation and sequestration. Literally, sequestration is the offset mechanism of trapping the atmospheric carbon in vegetation and in the soil by both natural as well as the human-induced system. Under the control of seasonal variation, carbon sequestration is also a result of capture and storage capacity. Thus, the process of sequestration is more closely linked with the land utilization practices of local people through the utilization of their indigenous know-how. The earth system has a tremendous capacity to retain atmospheric carbon through the geological formation and oceanic depositions but these all are fully controlled by nature's laws. Various scientists have carried out their works to assess the mechanism of carbon sequestration but land use related understanding and measurement the process of urban expansion in the light of CO₂ source-sink is still in paucity. Presently the systematic study on land cover and land use changes have got preferences in the research fields of spatial and change science (Vitousek *et al.*, 1997).

Globally, human society is consuming more resources from natural limits and squeezing the earth's natural assets (Livingstone, 2002). Human consumption among the other dwellers of earth surface is much more and it creates threat condition in environmental burden and risk. This situation has more highlighted in the urban areas where every dweller's security is found in threatening conditions (McManus and Haughton, 2006; Wackernagel, 2001). In this connection, Rees (1997) considered the city as an incomplete ecosystem. These threats crossed the former boundary of the urban places and generated ecological impacts too far beyond the built environment of the urban area (McManus and Haughton, 2006; Rees, 1997; Wackernagel and Rees, 1996a,b). In the urban area ecological footprint also calculates the equivalent land amount for per capita material consumption of inhabitant's functions. The approach of the ecological footprint is being popular dramatically in the developed country for the assessment of urban sustainability and environmental planning. Regarding this, the concept of the ecological footprint is a more successful approach (McManus and Haughton, 2006) and also a vital tool to measure and analyze the sustainable uses of the resource by the individual or population (IWM (EB) 2002). Generally, it measures the impact of resource consumption as well as a waste generation (McManus and Haughton, 2006). Therefore, it is a powerful indicator of demand for resources per global hectare area (gha) which compare with the supply of productive area (IWM (EB) 2002). On the other hand, it is a good technique to measure the impacts of resource utilization at various scales of study; it is suitable at the national level in one hand, works best at the city level (McManus and Haughton, 2006). According to Wackernagel and Murray (2004), ecological footprint considers 'the excess global demand over the global supply of nature's resources for human use' (McManus and Haughton, 2006). McManus *et al.* in their famous paper used the concept of an ecological footprint in a metaphoric way. They believed that it has a deep link with various earlier concepts; as for example, in 1917 Mark Jefferson indirectly used the concept of 'sustenance space of cities'. For the greater dependency of the English industrial cities upon the imported resources, Mahatma Gandhi observed that 'London needs half the world to keep it operating' (McManus and Haughton, 2006). In 1965, the Swedish academician George Borgstrom illustrated the idea of 'ghost acres'.

Expansion of built-up environment is a phenomenon relating to the development of a cultural milieu of the human society as well as it is a 'modern art' of human habitation. In the recent globalizing era, urbanization is occurring throughout the world with rapid changes in the urban morphology to the way of life of people. Concretization of land unit alters the nature of re-radiation from the surface, carbon dioxide (CO₂) generation, the aerosol concentration at a large scale. However, recently Indian cities have grown at an alarming pace and have encroached its surroundings, which accelerated the growth of population in the other surrounding urban centers. As a result, this situation brings forth changes in land use scenario in greater dimensions (Vasconcellos, 2001). As per the World Bank report (2010), the average footprint of CO₂ in India is 1.33 tCO₂e/capita in 1994 and in Kolkata, this scenario is 1.1 tCO₂e/capita in 2000. Although urbanization in India is characterized by many changes and it has a pivotal role in the nation's growth and development, but climate change is now beginning to influence urban development strategy (GoI, 2015). In the coming decades, Indian urban centers will work towards more productive and stronger rural to the urban linkage.

Subsequently, from an economic or market perspective, one has to distinguish between a mandatory market and a voluntary market. Prevalent for both markets is the trade with emission certificates: Certified Emission Reduction (CER), Emission Reduction Unit (ERU) and Verified Emission Reduction (VER). To achieve the goals as defined in the Kyoto Protocol, targeting with the minimal economic costs, the following flexible mechanisms were popularized for the mandatory engineering market i.e., Clean Development Mechanism, Joint Implementation, Emission trading. The Clean Development Mechanism and the Joint Implementation Mechanisms require for projects which cater the supply of emission reduction instruments; while Emissions Trading allows those instruments to be sold on international markets under the guidance of policy instrumentation. In this regard, the projects which are compliant with the requirements of the Clean Development Mechanism are controlled under the CERs process. The projects which are compliant with the requirement of the Joint Implementation Mechanism are monitored under the rules of ERUs.

At present, the status of CERs and ERUs is fully depended on emissions related trading. The demand for the CERs and ERUs being traded under the driver of (a) the crisis in national emission reduction obligations under the Kyoto Protocol and (b) lacuna among the entities obligated under local emissions reduction schemes. Nations which have failed to deliver their Kyoto emissions reduction obligation (United Nation, 1998) can enter Emissions Trading to purchase CERs and ERUs to cover their treaty shortfalls. These nations or group of nations can also create local emission reduction scheme which places mandatory CO₂

emission targets on entities within their national boundaries. Based on the CRS (2012) report, it is advocated that if the rules of treaty allow, the obligated nation/s may be able to cover all or any few reduction strategies by purchasing CERs and ERUs through Emissions Trading. While local emissions reduction rules have no status under the Kyoto Protocol itself, they play a vital role either in creating the demand for CERs and ERUs or stimulating the Emissions Trading and setting a market price for further emissions.

In contrast to the strict rules set out for the mandatory market, the voluntary market provides companies with different options to acquire emissions reductions as well as policy framing. A solution, comparable with the development of the mandatory market, has been prepared for the voluntary market is known as Verified Emission Reductions (VER). This measure has the great advantage to manage the critical result according to the quality standard for any projects but the certificate provisions are not registered by the governments of the host countries or the Executive Board of the UNO. Subsequently, high-quality VERs can be acquired at lower costs for the same project quality. However, at present VERs can't be used in the mandatory market. The voluntary market in North America is divided between members of the Chicago Climate Exchange (CCE) and the Over the Counter (OTC) market. The CCE is a voluntary unit yet has legal binding cap-and-trade emission scheme whereby members were committed to coping up the emission reductions and must purchase allowances from other members or offset excess emissions. The OTC market does not involve with the legal binding scheme and it has a wide array of buyers from the public and private realms, as well as special events that want to go carbon neutral. Being a carbon neutral one country can refer to achieve net zero carbon emission by balancing the measured amount of carbon released with an equivalent amount sequestered or breaching. On the Voluntary market, Renewable Energy Certificates (RECs) sold are quite contentious due to additional concern (Hamilton *et al.*, 2007). Siphoning off industrial gas for sequestration is considered picking the low hanging fruit; which is why credits generated from industrial gas projects and these are the cheapest in the voluntary market. The size and activity of the voluntary carbon market are difficult to measure (Hamilton *et al.*, 2007) and is fully governed by the policy instrumentation. In this framework, the European Commission (EC, 2018) has suggested different possibilities of carbon reduction through the adaptation of policy implementation and green technology.

Global Scenario of Land Utilization as Green Instrumentation

According to Andrew and Kaidons (2011), the concept of policy instrument within the frame of engineering domain acts with the help of three kinds of approaches; *firstly* the capping approach which imposes the quality of carbon emission along with the permissible limits of maximum emission. In this thought, the excess ejection of GHGs should be followed by the market price of emission. *The second* view propagates through the levy approach and it directly imposes of price valued upon the emission and this view also assumed that the excess charge will reduce the volume of emission, and the *third* approach directly controls the outflow of the greenhouse gases and it is known as a regulated approach. But after experiencing the policy and practices since the last two decades many governments have inclined to regulate price on the CO₂ emission in terms of market-based and relative cost adjustment. On the other hand developed countries were basically in favor of 'cap and trade' system; nevertheless, these all are experiencing too slowly and not to up to level with expected result (Carbon Market Data, 2009; Andrew and Kaidons, 2011). The use of pre and post-combustion captures are found in limited in the industrial sectors and oxyfuel combustion for CO₂ is presently in the demonstration stage in the advanced nations (Metz *et al.*, 2005). Besides these all economic instrumentation, parties of the Kyoto Protocol have enforced the policies that enhance the capacity of CO₂ absorb and allow to land through carbon sink process (The Royal Society, 2002). Initially, this protocol was not a comprehensive one in terms of sequestration but this was drawn up in the commitment period of 2008–2012 (Waran and Patwardhan, 2001). On the other hand, the United Nations Framework Convention on Climate Change (UNFCCC) in 1997 has focused the different issues related to the emission of GHGs and associated land utilization. And it is true that many human-induced activities produce far more carbon sink than its credit. However, the court regulation (article 3.4) of the Kyoto Protocol allows the provisions of carbon sequestration through the traditional practices of local people using their indigenous knowledge. Thus, the sequestration of this gas in any form is considered the effective strategy of land use policy but the volume of storage and sequestration permanency is the matter to the concern of people's perception. And in urban sectors, it is more vital to balance the carbon source-sink capacity. Categorically agriculture sector has the highest capability to sequester the CO₂ from the atmosphere. As a result, land-use instrumentation comes to play a vital role in disposing the excess CO₂ from the atmosphere.

The concentration of gaseous carbon in the atmosphere leads to the rise in average temperature in addition to incorporate different kinds of long-term environmental problems. Hence, it is difficult to formulate a universal consensus and adaptation policy to slew this problem (Andrew and Kaidons, 2011). But it is necessary to stay our planet alive. Presently, reduction of CO₂ is cognizant matter in the engineering platform. In every step of technological improvement strategies, it is a prime concern that the greenhouse effect performed gases should be less in the coming future. Most of the leading technological industries in the USA use two types of instrumentation regarding the low GHGs to trap the excess emission and these are either *Offsets instruments* which reduce direct emission of gases; or *Renewable Energy Certified instruments* which manage the indirect emissions. Chicago Climate Action Plan has also been introduced the forum focusing on the enforcement of the energy efficiency buildings. In the report of U.S. Energy Information Administration (2010), it is found that urban trees have increased its capacity to CO₂ sequestration from 57.1 in 1990 to 93.9 million metric tons per year in 2008 (USEIA, 2011). Whereas, the Carbon Tax, a cap-and-trade system, and vintage model are considered prime attempts which controlled carbon emission in the UK for the last two decades (Ingham and Ulph, 1991). On the other hand, various types of policy instruments are performed as new paths of green technology in Australia

under the Carbon Pollution Reduction Scheme (Freebairn, 2016). Apart from 'infrastructure-21 Summit', a new integrated approach was adopted by the national spatial plan of Australia. There was a wide range of planning initiatives incorporating state, regional and local consensus through urban planning in connecting the climate change adaptation like Victorian Climate Change Green Paper, South East Queensland Climate Change Management Plan, North Queensland Regional Plan 2025, Sustainable Sydney 2030 etc. It was the first time in 2008 when built-environment was paid more attention to the community resilience by industrial insurance (Norman, 2010), but CO₂ footprint in association with land use dynamics is still neglected. Canada has also practiced the same adaptation measures along with Building Resilience to Climate Change in Human Settlement Programme in the year of 2009. In developing countries, this is very difficult to run an effective emission controlled scheme. It is true that the problem associated to score the green success lies in social and political inertia as well as economic sacrifices (The Royal Society, 2002). Similarly, only a few have been adapted for the betterment of urban climate. A carbon neutral sustainable city plan was proposed for Shanghai, China. In India, carbon sequester land utilization policy is fully absent but the scientific study regarding its understanding is going on. As for example tree patches in Puna city absorbed only 2% carbon per year and causing 98% overload in its immediate surroundings (Waran and Patwardhan, 2001). Whereas Florence in Italy has contracted 6.2% of the direct carbon emission through its 29.1 sq km green space (Vaccari et al., 2013).

Nature and Scope of Land Instrumentation in Kolkata

Human-induced modification of land cover and land use results in the fragmentation of landscape and large-scale environmental degradation since the last four decades in and around the Kolkata city. So, this is the right time to study the green land transforming the urban environment in the context of the impact of land modification and development of CO₂ source-sink area within the arena of fragile ecosystems like that found in the context of Kolkata. Kolkata, having one-third population residing in the informal settlements is now experiencing rapid spatial as well as economic expansion (Colenbrander et al., 2016). The process of urbanization creates a high rate of energy inflow in urban ecology and alters the nature of surface-air interaction system to create the phenomenological changes of local climate. In the case of Kolkata Municipal Corporation (KMC), leading metropolitan urban center in eastern India, the advancement nature of built-up environment posed threats to the several ecological function of water bodies within as well as immediate surroundings of urban limits, fragile ecological relation and ultimately encroaching upon the green spaces (Haque and Bandyopadhyay, 2012). KMC is not a walled city but it is almost bounded in all sides either by the natural systems (like the Hugli River on its west and the East Kolkata Wetlands to its east). Since the last four decades, the fringe area of this metropolitan center has absorbed more population than it's downtown the city has experienced a rapid outward extension of housing infrastructures and structural modification (Pathak, 2011). Owing to the high rate of population concentration the nature of city limit of KMC is *over-bounded* for a long time i.e its built environment has exceeds its boundary. So, the outer wards of the KMC, compare to the inner-city wards have gained population along with the infrastructural development which creates an environmental cost of urban activities (Haque and Bandyopadhyay, 2012; Shaw, 2015). Thus, the expansion of city limits reveals both spatially and ecologically, that the quasi-natural ecosystem situated in its immediate surroundings has been impacted through the extension of the built-up surfaces. Here 59% of people used modern energy sources and the remaining depends on fossil fuels like kerosene and solid fuels (Colenbrander et al., 2016; ALGAS, 1998). As a result, energy utilization capacity per unit area has increased vigorously which has exaggerated the release of carbon in the local atmospheric system and created different Local Climatic Zones. As per the Central Pollution Control Board daily report, it is observed that the month of November 2018 Kolkata has experienced the highest number of 'red category' days in terms of Air Quality Index (AQI). Sometimes the city's air quality was worse than Delhi's (TOI, 2018). In and around the KMC jurisdiction, the extended built-up space replaced huge numbers of tropical wetlands, agriculture, and open land. The air quality has also been declined because of the high rate consumption of diesel fuel. Besides, the following concepts are playing important roles, which are beneficial to urban land use planners and other adjunct development activities in terms of green land use management system.

- (1) *The implication of 'land instrumentation' analysis at the micro-level study:* Efforts regarding municipal facilities in the process of policy making are now becoming one of the vital principles in urban sustainability and ambitious urban planning. Within the limits of the municipal boundary, intra-zonal variations of urban ecology are also becoming popularized with time especially in the arena of developing the region. While the attention of sustainability and overall urban development is welcome, the spatial distribution of land use scenario should be emphasized from the knowledge of the technocratic solution. Integration of micro-level spatial and spatial data along with the statistical analysis through the soft-computing technologies portrays the contemporary situation of urban ecosystem spatially CO₂ source and sequestration nature of land segments. In this concern 'land use' acts as an instrument. Research regarding the carbon release and sequestration creates the fundamental and scientific know-how underpinning the scope of land instrumentation.
- (2) *Green aspect of the micro-level planning:* In the recent economic and environment relationship, urban center play as a pivotal role regarding the unprecedented flow of resources, wastes, trade products, services, capital, and labor. This interconnected relationship creates environmental problems involving major damage to the tropical ecosystem in the study area, which is basically unprecedented and not replenishable. Ultimately different patches of micro-climate will generate automatically and develop unique types of CO₂ source and sink area. Under this circumstance, this work advocates some strategic ways of land instrumentation planning through integrated urban development planning.

Fig. 1 Major LULC characteristics of urbanization in Kolkata.

- (3) *Controlling the negative characteristics of Urban Land-use:* As KMC has a long experience of colonial history and has grown without any proper planning, its central part has already become a problematic area and started to decay due to numerous negative reasons. The proper and systematic understanding regarding the green land utilization process can revitalize and renew these land segments with the integration of science, technology and society inputs.
- (4) *Management of the ecological cost of land transformation:* The very word 'ecological cost of land transformation' is necessary for the management of urban space into two different ways. *Firstly*, conservation and redevelopment of the existing ecological hot-spots like water-bodies, green spaces, segments of open land and pockets of biological habitat etc. which have already been fragmented in nature, shrinkage in its spatial extent and have a weak ecological function. Because these were all treated as areas of CO₂ sink in the compact urban domain. Secondly, the creation and rejuvenation of CO₂ sequestration spaces within the contiguous built-up environment through which carbon footprint will be maintained. The attempts to create this sequestration should be eco-friendly to the local area in terms of soil, groundwater, and climate. The efforts regarding the beautification and landscape design related activities in the study area have been done with the efforts of super-imposing the foreign species which do not sustain the local ecosystem rather created environmental degradation.

The process of urbanization in Kolkata leads two different styles ([Fig. 1](#)) and it is also characterized by horizontal dominance of built-up extension. [Colenbrander et al. \(2016\)](#) have estimated the increasing nature of GHGs emission in terms of total emission, per unit and per capita energy consumption for the coming decade, although it will be declined with the GDP rate. The land utilization practices during the last five decades in KMC also create different types of changes. The details of major changes are described below:

- (1) A number of *wetlands* in the extended part of KMC have dramatically been consumed by built-up environment under the process of urban extension. Since 1957 near about 50% water bodies including wetlands have been altered to built-up uses. There were two large wetlands in the eastern portion of KMC popularly known as Kadapara (means muddy-hamlet) in ward no 31 and three out of four old wetlands in the central portion of Wattgunge (under ward no 75) have totally vanished owing to the same reason. Wetlands in Paharpur and Taratala region (in Ward No. 80) have utmost (nearly 80%) disappeared due to the encroachment of built-up structures. Rest of the area has transformed their water bodies into either Open Land, Grass Covered area or Tree Covered area. The same situation is also critically found in Anandapur, Patuli, Mukundapur, Garia, Jadavpur area as well as both sides of E. M. Bypass for the urbanization. Wetland in the all most of the wards located in the east and south-eastern periphery of KMC are found with the fragile condition. Land fragmentation, garbage dumping, filling of water bodies through solid waste, illegal encroachments etc. have been sighted during the field investigation in central and northern wards of KMC. As a result, the scope of decarbonification has become limited; only the patches of tree and grass covered area have the carbon intake capacity.
- (2) The process of urbanization through the redevelopment and rejuvenation of the built-up environment grabbed the *ponds* in the KMC. Wards located in the northern portion of the study area filled up most of the ponds. Here maximum ponds have been left neglecting to maintenances and also surrounded by buildings with no natural bank. From the ecological view point, this was more sensitive for the pond ecosystem. Similarly, some big patches of the pond are found in the Port area and the medium or small patches are shown central and south-western area, mainly located at the Metiabridge region. It is remarkable that the total area of Ponds has increased in Taratala (about 1% to total ward area) due to the development of fisheries and aquaculture activity of Mudiali Fisheries Estate but it happened only in the pocket area. This type of change has been mainly noticed on the eastern side of KMC. Eventually, the activity of pond filling still going on basically for the different types of developmental activities. A very negligible portion of earlier Pond segment has converted into Open Land category. Ponds in and around the Sinthi, Maniktala, Kasba, Kalikapur, Jodhpur Park, Bansdroni, Behala, Taratala are found in a stressed condition. During the field observation, it is found that almost the entire numbers of ponds are structured and fenced by concrete banks. Previously ponds associated with its banks performed a unique function of the ecosystem to detain high amount of CO₂ from its surrounding but from the ecological viewpoint presently all these became functionless.
- (3) It is revealed that *Open Land* was the predominant land cover unit in the year of 1957 in all the wards of the added area of KMC. Comparatively, wards situated in the central portion have contained nearly zero open areas. During the 1980s the extensive open land was situated in the south-eastern fringe of the ward, coverage, and utilization of open land for the

Table 1 Ecological footprint in selected wards under different variable

Variable	The ecological footprint of selected wards (cubic metre/person/year)				
	Ward 31	Ward 75	Ward 80	Ward 93	Ward 128
Food	1158.221	966.1535	2562.849	2176.1	2041.604265

Source: Compiled by authors based on LULC output and primary survey in 2013.

purpose of grass and tree cover maintenance is about very less and it has been used for beautification and recreation purposes, i.e., 'parks and gardens'. During the field study, open land was found to be used for dumping of garbage. An elongated patch of vacant land is found along the western side of D. H. Road. It is located on the south-western side of the study area. Another elongated open land has been napped along the western side of the Becharam Chatterjee Road situated at the Ho-Chi-Minh and Basudebpur crossing. Rest open lands were marked in the isolated condition in the northern portion and situated in the eastern side of KMC. During the last five decades, this class of land utilization has been totally altered its characteristics i.e., became built-up structures. Because of its roadside location in an eastern & south-eastern portion of the Ward this class of land utilization had attracted various developmental activities.

Both Tree Covered, Lawn and Grass Covered condition have found quite environmentally stress situation with a fragile ecosystem. Owing to the developmental programme and renovation activities of roads, the non-native vegetation species have been plated dramatically. Openland has been formed in the new places comparatively previous vegetation area which shows the indication of unplanned land conversation. In one word the uncontrolled extension of the built-up horizon in KMC exaggerates the CO₂ generation source replacing the CO₂ sequestration facilities. The following table shows the ecological footprint of the five selected wards on KMC in the year of 2013. For the discussion of CO₂ footprint, except wards located in the central portion of KMC (ward 75) due to the vegetational occupancy all have a high level of absorption capacity in 1957; but in 2013 carbon generation area has increased dramatically. For example, ward 93 has a drastic change in terms of carbon generation rather absorption. From the ecological viewpoint, it is noted that CO₂ in the atmosphere is fully controlled by the direct process of photosynthesis and respiration, which are also been operated by land utilization practices. In the tropical monsoon climate (the light value of PAR) high rate of photosynthesis is found between 25°C to 35°C and the average temperature of Kolkata is also ranged between these value with high relative humidity condition. Under these circumstances, a strong mesophyll cell contained tree absorbs 20 µmol CO₂ per sq. metre per second by photosynthesis process, on the other hand, it produces 7 µmol CO₂ per sq. metre per second. So the net photosynthesis value is 13 µmol CO₂ per sq. metre per second (Smith and Smith, 2007). Thus the level of CO₂ concentration in and around the Kolkata urban area will be higher along with the other GHGs showing the variety layout of spatial concentration.

The nature of ecological footprint in KMC has been assessed in a few selected wards using both primary (i.e., household variables) and secondary (i.e., LULC) information under the framework of GIS platform. From Table 1, one can understand the ward level scenario of ecological footprint regarding various parameters of LULC category. All the values are showing the average condition of ecological footprint in terms of cubic metres per person per year. As the spatial concentration of population is high in ward no 80 (Port area and Taratala) and most of the people are engaged as daily laborers in port activity and informal service sectors, the total value of ecological footprint is comparatively high than other selected wards. The same condition is also found in the case of ward no 93, having the second highest value this ward shows of high concentration of population in Lake Garden, Jodhpur Park, and South City area. On the other hand, Ward No. 75 (Wattgunge and Hastings area) shows the minimum value of ecological footprint because of the presence of prohibited areas of stables, defense sector, cantonments houses in Hastings area and the existence of slums and warehouses in Wattgunge area. For the consideration of CO₂ footprint and its temporal changes, ward no 93 has shown extreme changes for the remarkable alteration of land utilization system (Table 2). In the year of 1957, the CO₂ absorption area was more than ten times larger than carbon generation area. Presently carbon generation area is nine times larger than its absorption/sinking area. Regarding the LULC change detection, the CO₂ source/generation land area in 2013 have drastically increased to replace the CO₂ sink/absorption capacity bearing area. Vertical use of urban built-up space is also responsible for creating more carbon-dioxide in relation to land utilization. Other than these five selected ward areas, central

Table 2 Temporal variation of CO₂ footprint in selected wards of KMC in terms of LULC

Ward no.	Area in 1957			Area in 2013		
	Absorption (a) sq. metre	Generation (g) sq. metre	Footprint (a/g)	Absorption (a) sq. metre	Generation (g) sq. metre	Footprint (a/g)
31	1,131,809.431	327,465.698	3.46	236,561.3314	1,222,714.331	0.19

Source: Compiled by authors based on LULC output from Sol map and primary survey in 2013.

Note: the value a/g indicates the areal dominance for carbon generation or absorption; if the value is 1, then it shows a balance condition; more than 1 value marks the dominance of carbon assimilation and less than 1 value depicts the dominance of carbon generation capacity under land utilization practices in KMC.

Fig. 2 Distribution of CO₂ absorption area in KMC: (A) spatial variation of parks with population concentration, (B) satellite output of CO₂ absorption area along with generation of the built-up environment. Source: Haque, S.M., 2013. Urbanization around Kolkata Metropolitan Core and Its Impact on Landuse Changes: A Geospatial Analysis (Unpublished PhD Thesis). Central library, University of Calcutta, p. 172.

Kolkata has similar condition depicting compactness of built-up infrastructure (Fig. 2(B)) and high density of population concentration. Owing to the location advantage, KMC did not contain this CO₂ for a long time because of the strong monsoon wind flow from July to October and heavy precipitation. But people in the central Kolkata faced uncomfortable weather during the late winter and early summer. As the immediate surroundings of the built-up surface in this period bear a high amount of CO₂, it absorbs an excessive amount of long-wave surface reradiation which also develop the strong Urban Heat Island effect. Long duration existence of this type of effect creates an unmanageable demand on energy consumption to modify the indoor environment of the buildings and again it could trigger the carbon generation procedure. The situation of this type of local climate and its land-use controlled has already been advocated by Stewart and Oke (2012).

Land Use Sustainability and Balanced Carbon Footprint

Environmentalists, ecologists, and scientists have already been advocating that an urban area has shown climatic differences compared with its immediate surroundings as well as rural areas (Nowak, 2000). Lomas (2006) measures the Carbon Footprint in UK Cities through different types of mapping, modeling tools. The World Bank (2012) shows the probable capacity of carbon sink in the agriculture field and its allied soil segment. Nowak and Crane (2002) estimated that the urban trees have the role of sequestrators in ten USA cities through the carbon storage ranges from 1.2 million ton (in New York, NY) to 19,300 ton (in Jersey city) and the national average is 25.1 ton per hectare to 53.5 ton per hectare. The US Department of Agriculture has advocated the measurement guideline for the sequestration of forest carbon by the public and private entities to register the GHGs (Pearson and Brown, 2007). On the other hand, Aricak et al. (2015) examine the carbon biomass above the ground surface in the dry region of Turkey through

Fig. 3 Conceptual framework of green LULC practices to achieve a balanced carbon footprint in Kolkata through LULC practice. *Source:* Prepared by authors.

the Remote Sensing techniques. [Liu et al. \(2012\)](#) and [Velasco et al. \(2013\)](#) have measured the nature of carbon flux in the urban neighbourhood in the tropical region. The nighttime surface influx along with the seasonal variation of CO_2 along with CH_4 in urban areas of Southern Poland has also been studied by [Zimnoch et al. \(2010\)](#).

Based on the above discussion in the urban development perspective, now scientists are realizing the significance of study the consequences of the carbon footprint for the spatial development of urban infrastructures. Urbanization in the context of climate change is being more vulnerable with the development of carbon source triggered land use practices. Though the different forms of footprint counting are established in the domain of ecological and environmental science, land-use and land-cover controlled assessment of carbon footprint has more vital for the geographical understanding of the micro-level study. India is becoming more urbanized in the coming future with the limited available area and Kolkata is naturally bounded urban center. River Hooghly confined its western limits, an old urban center known as Baranagar is situated its northern side and the eastern boundary is circled by ecologically fragile Ramsar area East Kolkata Wetland. Subsequently, to achieve the sustainability of this metropolitan center it is essential to minimize the carbon generation activity along with its maximum absorption capacity and citizens have to practice the balance strategies of CO_2 footprint reduction. The essential steps to achieve a balanced carbon footprint in Kolkata are sketched below.

Conclusion

In the complex urban landscape, the development induces activity has always promoted the formation of the concrete horizon is associated with the creation of a built-up environment which is basically impervious and flourishes long-wave radiation from the

surface. Besides, the compact built-up area has no scope of CO₂ sequestration capacity except the superimposition of green vegetation in it and it is not easy to accept that all types of vegetation have the equal power to operate CO₂ absorbing capacity even in the same climatic situation. Uncontrolled and unsystematic land transformation in the leading metropolis has experienced significant role in CO₂ generation and thermal energy production. So, the construction activity associated with high rises is not free from all types of environmental as well as ecological constraints. Metropolitan Kolkata, like other leading urban centers, has numerous climatic problems and it has already been faced with different environmental difficulties. For the assessment of these kinds of environmental problems systematically, carbon footprint will consider a vital measuring tool for long term sustainability of a compact urban area. Urban nodes allowing the relationship with its vast hinterland, create the barrier for its green development and have a strong inflow-outflow mechanism of the energy demand as well as resource requirement interaction. On the other hand, the target of green development in the compact urban area will largely control by the introducing of green LULC practices. Where the practices of land instrumentation (Fig. 3) is more suitable for the limited and controlled consumption of energy required infrastructures, symbiotic association with green patches, alternate use of environment degraded materials, promotion of more green building, construction of urban landscape to support local climate and wise use of natural resources etc. Like the other engineering instruments, utilization of land parcel (as prescribed in Fig. 3) should be treated as a green engine to build more carbon absorption. With the smooth opening of this type of enviro-centric and green practice, urban landscape will improve its environmental quality in the coming future. Eventually, the people should be made aware of ways to control the emission with requisite perception change and pursue the green land instrumentation within the compact urban settings.

Introduction

Rapid industrial development and human growth has led to the huge increase in fossil fuel consumption, causing a dramatic CO₂ concentration in earth atmosphere. It leads to significant increase in average global temperatures over the past several decades (Oelkers and Cole, 2008). This temperature increase has been linked to global warming and climate change like heavy precipitation events, including hurricanes (Groisman *et al.*, 2004), and rising sea levels due to melting of ice glaciers (Manabe and Stouffer, 1994). A temperature also leads to ocean acidification, effects on global ecosystems (Cole and Monger, 1994), flora and fauna distribution (Mckenney *et al.*, 2007), extinction of numerous species and human health impacts (Patz *et al.*, 1996). Weather events (Table 1) such as extreme temperature difference as high temperature in Australia recorded in January 2014 (54°C) and Canada faces extreme cold storms (~ -50°C) at the same time. In the 2005–2006, hurricane Katrina in the United States and the droughts, bushfires, snow (almost simultaneously) in Australia makes climate change as global agenda. As a result of that, there were growing scientific, economic and political debates to the issues related to CO₂ management (Table 2). Kyoto protocol (1997) is a keystone document in international climate change policy which aimed at phased reduction of greenhouse gases (GHGs). The targets were to reduce GHGs emissions about 5% below the 90s. In December 2009, interested countries met in COP-15 (the Copenhagen Protocol) to draft for this overarching of determined and direction of long-term changes to limit global warming.

Table 1 Timeline of tragic events related to climate change

Sl. no.	Year	Tragic events	References
1	1889	The Johnstown Flood killed 2200 people when the South Fork Dam holding back Lake Conemaugh broke	(Perkins, 2009)
2	April 26, 1989	The Daulatpur–Saturia, Bangladesh Tornado occurred in the Manikganj District, Bangladesh and was the costliest and deadliest tornado in Bangladesh's history. There is great uncertainty about the death toll, but estimates indicate that it killed around 1300 people	(Cerveny, 2006; Jonathan, 2008)
3	1931	The Huang He (Yellow River) in China floods particularly often. The Great Flood of caused between 800,000 and 4,000,000 deaths	(Pietz, 2002)
4	November 11, 1970	Bhola cyclone struck East Pakistan (now Bangladesh) and India's West Bengal and killed Up to 500,000 people	(Paula Ouderm, 2007)
5	2003	A deadly summer heat wave in Europe kills more than 30,000 people	http://www.pbs.org/newshour/indepth_coverage/science/globalwarming/timeline.html
6	December 26, 2004	The earthquake triggered a series of devastating tsunamis along the coasts of most landmasses bordering the Indian Ocean, killing over 230,000 people in fourteen countries	(Paris <i>et al.</i> , 2007)
7	2005	Awareness and concern about global warming rises in the U.S. after a tough storm season, including <i>Katrina</i>	http://www.pbs.org/newshour/indepth_coverage/science/globalwarming/timeline.html
8	2008	A 60-square-mile section of the Wilkins Ice Shelf breaks from the coast of Antarctica	http://www.pbs.org/newshour/indepth_coverage/science/globalwarming/timeline.html
9	February 27, 2010	The 8.8 magnitude Chile earthquake and tsunami cost 525 lives	http://earthquake.usgs.gov/earthquakes/eqinthe-news/2010/us2010tfan
10	April 27, 2011	One-day record of 188 tornadoes that killed 339 people, including 41 in Tuscaloosa, Alabama	http://towardfreedom.com/environment/2530-lethal-weather-the-rise-of-natural-disasters-due-to-climate-change
11	2011	Tōhoku earthquake and tsunami registered a moment magnitude of 9.0. The death toll from the earthquake and tsunami is over 13,000, and over 12,000 people are still missing	(Chai, 2011)
12	2012	according to The National Climatic Data Centre, Iowa is have more extreme rainstorms – Rainstorms are 35% more frequent in Iowa since 1948	(Willcox, 2012)
13	2012	Every month through August brought record high temperatures in America, with frequent triple-digit heat days	(Wiltgen, 2012)
14	16–17 June 2013	Lake outburst and debris flow disaster at Kedarnath, Uttarakhand, India: Killed more than 6000 people	(Guha-Sapir <i>et al.</i> , 2014)

Table 2 Different treaties related to CO₂ management

<i>Sl. no.</i>	<i>Year</i>	<i>Events</i>	<i>Issues</i>
1	1971	SMIC conference	There is a requirement of organized research effort to prevent serious global change
2	1979	The first World Climate Conference (Geneva)	World Climate Program established
3	1985	Joint UNEP/WMO/ICSU Conference	Role of Carbon Dioxide and other Greenhouse Gases in Climate Variations and Associated Impacts
4	1987	Montreal Protocol of the Vienna Convention	Project international restrictions on emission of ozone-destroying gases
5	1988	Toronto conference	Called for strict, specific limits on greenhouse gas emissions
6	1992	Intergovernmental Panel on Climate Change (IPCC)	192 countries signed for stabilization of greenhouse gas to avoid climate change
7	1992	The United Nations Conference on Environment and Development(Earth Summit)	First unified effort to get to grips with global warming and leads to negotiations
8	1992	UN Framework Convention on Climate Change(Rio de Janeiro)	- Stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system - Ensure food production is not threatened - Enable economic development to proceed in a sustainable manner "A discernible human influence" on the Earth's climate
9	1995	IPCC's Second Assessment Report	Developed nations agree to cut greenhouse gas emissions by at least five per cent by 2012
10	1997	Kyoto Protocol	- US later refuse to take action. Developing nations, including China, have no formal binding targets - Rich countries agree to take action first on the model of the Montreal Protocol - Diplomats did not pay attention to the financial implications of the emission trading
11	November 2000	A two-week conference at the Hague	- Try to produce an agreement on measures to fight global warming - U.S. and EU cannot agree on necessary measures
12	2001	The IPCC's Third Assessment Report	Project is new and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities
13	2007	The IPCC's Fourth Assessment Report	World will have to end its growth of carbon emission within seven years
14	2008	Climate Change Act	UK passed the Climate Change Act committing the country to cut greenhouse gas emissions to 80% of 1990 levels by 2050.
15	2001	Bonn meeting	Develop mechanisms for working towards Kyoto targets
16	2007	Fourth IPCC report	- Warned that serious effects of warming have become evident - Cost of reducing emissions would be far less than the damage they will cause
17	December 2007	UNFCCC meets, Bali, Indonesia	Proposed for a roadmap for a new post-Kyoto climate change treaty
18	December 2009	UN Climate Change Conference, Copenhagen, Denmark	- Try to negotiate binding agreements - Hopes of avoiding dangerous future climate change
19	December 2010	The UN Climate Change Conference, Mexico	- Deep cuts in global emissions in order to limit global average temperature rise to 2°C - Parties agreed to keep the global long-term goal under regular review and consider strengthening it during a review by 2015, including in relation to a proposed 1.5°C target
20	28 November–11 December 2011	The UN Climate Change Conference in Durban, South Africa	- Establishment of a second commitment period under the Kyoto Protocol - Launched the new ADP with a mandate "to develop a protocol, another legal instrument or an agreed outcome with legal force under the Convention applicable to all Parties"
21	August 29–31, 2012	Second Nordic International Conference on Climate Change, Helsinki	- Agreement on the operationalization of the GCF - Identify common ground between adaptation research and adaptation decision-making by comparing experiences
22	2013	Climate Change Conference, Convention Centre, Palmerston North, New Zealand	- Reporting new insights and revealing key gaps in knowledge - Opportunity to consider challenges the research and end user communities face when dealing with climate change
23	June 22–23, 2013	Australian Climate Action Summit, Sydney	- Awareness of the severe impact of coal and coal seam gas industries on climate, health, land, water and air - Benefits of moving to clean renewable energy
24	July 15–16, 2013	ICCCGW 2013 Stockholm, Sweden	Discuss the practical challenges encountered and the solutions adopted

(Continued)

Table 2 Continued

Sl. no.	Year	Events	Issues
25	June 19–21, 2013	Transformation in a Changing Climate, Oslo, Norway	• Diverse perspectives on transformation, and to generate cutting-edge discussions on deliberate, ethical and sustainable transformation • Complex global challenges associated with climate change
26	30 Nov 2015–12 Dec 2015	United Nations Climate Change Conference, COP 21 or CMP 11, Paris, France	• 195 countries agreed on a plan to reduce emissions of CO₂ and other greenhouse gases

Intergovernmental Panel on Climate Change (IPCC, 2000) which proved the GHGs emission was the major cause of global warming and fixed responsibility of major emitters that is developed countries. United Nations Framework Convention on Climate Change (UNFCCC) established in 1992 to provide a framework for policy making to mitigate climate change based on scientific agreement. The ultimate aim of the UNFCCC, as stated in Article 2, is stabilization of atmospheric greenhouse gases at a reduce level to prevent dangerous anthropogenic climatic influence. Hence, need of global effort to reduce the amount of CO₂ emission from the source has become increasingly emphasized as a primary environmental concern and sustainable carbon dioxide management practices are essential to fight long term climatic change issue.

Carbon dioxide is responsible for about half of the observed greenhouse effect (Rodhe, 1990). Arrhenius is the first to quantify the contribution of carbon dioxide to the greenhouse effect in the atmosphere. According to him water vapor and carbonic acid (resultant from the hydration of CO₂) plays dominant role in the absorption of small fraction of the solar radiation. Arrhenius refers to carbon dioxide as “carbonic acid” (Arrhenius, 1896). From experimental carbon management research to industrial and environmental applications, the efficient reduction of CO₂ has attracted growing international interest. The aspects behind the CO₂ transformation to valuable products like chemical and fuel is attractive towards sustainable carbon management, can promote recycles of CO₂ and balances anthropogenic emissions (Milani *et al.*, 2015). Sustainable carbon management plans should have both general and experimental aspects (Pant *et al.*, 2017). Includes: (a) Reduce emission; (b) maximum environmentally sound (3R) reuse, reduce, and recycling; and (c) increase energy efficiency, promoting energy conservation; increasing the usage of low carbon containing fuels (Shove, 2017) (d) turning carbon dioxide into valuable products with atom economy. Experimental carbon management plans involving various physical, chemical and biological approaches with limitation in terms of research level and economic feasibility.

The Global Carbon Cycle

Carbon presents in four different global C pools, namely, atmospheric, oceanic, fossil and terrestrial. Natural and anthropogenic activities can influence the total carbon stock by changing carbon cycle. Its current overall concentration of CO₂ is ~ 400 parts per million (ppm) compared with pre-industrial levels ~ 280 ppm by volume (Wisniak, 2002). Fossil fuel combustion and cement production are the main sources of global emissions of CO₂. Global net CO₂ emissions from human activities such as land-use change, including deforestation agricultural use, including open burning of cleared biomass are more difficult to update annually. Combined evidence from land cover change, fire activity, deforestation lead to net emissions rate were $0.9 \pm 0.5 \text{ Pg C yr}^{-1}$ in 2011 (IPCC, 2005).

The atmosphere containing $\sim 3.0 \times 10^{15} \text{ kg}$ (3000 Gt), of CO₂ and world's oceans contain $\sim 39 \times 10^{15}$ (39,000 Gt) of C, while $\sim 2.0 \times 10^{15} \text{ kg}$ (2000 Gt) C present in soils, vegetation and detritus (Fig. 1). Carbonate rocks (limestone, marble, chalk) contain $\sim 65,000,000 \text{ Gt C}$. So, only $\sim 0.001\%$ of atmosphere–ocean – upper crust system carbon present in the atmosphere (Holland, 1978). Vegetations play an important role in global carbon cycle through fix carbon dioxide *via* photosynthesis process. Land plants contain 250 times more carbon than aquatic plants. It is estimated that the exchange rate of carbon between surface ocean and atmosphere is about 90 Gt and 110 Gt with terrestrial vegetation (Houghton, 2007).

Natural process can lead to the release of CO₂ to the atmosphere from land and water includes animal and plant respiration, and the decay of vegetation where oxygen and nutrients are converted into CO₂ and energy.

Global Carbon Budget

The “global carbon budget” refers to the net C transition due to the uptake and return in the various pools. CO₂ emissions from fuel combustion and cement production (E_{FF}) and the CO₂ emissions from anthropogenic activities on land including land use, land-use change pattern and forest fire are reported here main sources of CO₂ emission (Table 3). The main components of the CO₂ budget are included CO₂ emissions sources like, (1) fossil fuel combustion and cement production (E_{FF}), (2) the CO₂ emissions resulting from land use changes (E_{LUC}) (Figs. 2 and 3) the growth rate of CO₂ in the atmosphere (G_{ATM}), and the uptake of carbon dioxide by the “CO₂ sinks” in the ocean (S_{OCEAN}) and on land (S_{LAND}). The balance between emissions rate of CO₂ and their partitioning among the all pools like atmosphere, ocean and land can be explained by following equation. The decadal mean of the anthropogenic CO₂ budget is given below (Quérel *et al.*, 2012) (Table 4).

$$E_{\text{FF}} + E_{\text{LUC}} = G_{\text{ATM}} + S_{\text{OCEAN}} + S_{\text{LAND}} \quad (1)$$

Fig. 1 Estimate of the global pools and fluxes. Reproduced from Pant, D., Sharma, V., Singh, P., *et al.*, 2017. Perturbations and 3R in carbon management. *Environ. Sci. Pollut. Res.* 24(5), 4413–4432.

Table 3 Global Carbon sequestration (Gt C/yr) by different process

Process	Carbon uptake	Carbon return	Net carbon dioxide removal	References
Soil vegetation	123	Plant respiration: 60 Decaying biomass: 60	3	(Farrelly <i>et al.</i> , 2013)
Ocean photosynthetic organisms	92	Respiration + decaying: 90	2	(U.S. Geological Survey, 2010)
Volcanic emission	–	–	0.13	(Scholes <i>et al.</i> , 2009)
Human activities	–	–	4.2	

Fig. 2 Decadal mean of the anthropogenic CO₂ emissions. Reproduced from Quéré, C.L., Andres, R.J., Boden, T., *et al.*, 2012. The global carbon budget 1959–2011. *Earth Syst. Sci. Data Discuss* 1107–1157. doi:10.5194/essdd-5-1107-2012.

Fossil fuel emissions of atmospheric carbon dioxide enhanced about 29% in between year of 2000 and 2008 from the fuel combustion and international trade of goods and services. Some other industries are also contributed to global carbon emission (Fig. 4).

Fig. 3 Decadal mean of the anthropogenic CO₂ sink.

Prepared by Working Group III of the Intergovernmental Panel on Climate Change. In: Metz, B., *et al.* (Eds.), Cambridge, U.K: Cambridge University Press.

Perturbation

Irregularity in changing the different C pools data cannot be ignored toward carbon mitigation and it creates the perturbation in the global C cycle. The perturbation of global carbon cycle can be categorized into the following categories (**Table 5**).

As per world meteorological organization world data centre for greenhouse gases, perturbation in CO₂ concentration (%) in various pools per decade given in **Fig. 5**. Carbon dioxide perturbation in different pools like atmosphere, oceanic and terrestrial is effecting total atmospheric CO₂ concentrations over the last five decades due to human activities and natural process. Human activities like fossil fuel combustion and cement production takes a major part of the current CO₂ perturbation followed by the atmospheric emissions, while terrestrial and oceanic pools showed less CO₂ perturbation than other pools. So, it is important to consider CO₂ perturbation is also for sustainable carbon management practices (**Fig. 6**).

Table 5 Example of main sources for Carbon dioxide perturbation

Sl. no.	Perturbation	Example
1	Biological perturbation	- Archaea/bacteria population is responsible for converting organic matter to CH₄ via anaerobic reduction and affects the oceanic and terrestrial carbon cycle - Rice paddies amplify the level of CH₄ in the atmosphere through wetland emission - Change in the number of archaea/bacteria, net primary productivity, rice paddies, wetland emissions, and loss of biological diversity are the events responsible for the perturbation in the biological carbon cycle
2	Geological perturbation:	Volcanic eruption and metamorphism of rocks are always uncertain and responsible for carbon cycle perturbation (Fan <i>et al.</i>, 1998; Pearson and Palmer, 2000)
3	Oceanic perturbation	- The enhanced supply of nutrients from land are continuously increasing the coastal productivity, temperature, organic matter burial, and gas hydrate recharge (Dickens, 2003; Lerman <i>et al.</i>, 2004) - Organic matter, dissolved phases, and authigenic carbonate in the oceans (Dickens, 2003) can result in oceanic perturbation
4	Missing carbon sink perturbation	Carbon stock data in tropical forests and northern mid latitude forests
5	Miscellaneous	Forest fire, bush fire, oil fire, leakage of CO₂ from storage sites and pipelines result in accidental emission of CO₂ to the atmosphere and affect carbon concentration

**Fig. 5** Percentage of CO₂ perturbation in different pools.

Carbon Mitigation Pathways

Direct Carbon Sequestration Pathway

This carbon sequestration approach is a most potential technology for reducing large scale CO₂ mitigation from point emission sources before it is released to the atmosphere. Pre combustion capture, post combustion captures and oxyfuel combustion are the main methods for direct carbon sequestration of CO₂ from emission sources. Pre combustion capture involves the removal of carbon from the fuel before the fuel is combusted through gasification and other methods, while post combustion capture is involve removal of CO₂ from gas stream. Oxyfuel method is the combustion of fossil fuel in presence of a purely oxygen environment (Buhre *et al.*, 2005; Hadjipaschalis *et al.*, 2009).

Depending on the removal process, various technologies for CO₂ separation from emission sources can be used, including absorption, adsorption, membranes techniques, and hybrid applications (Fig. 7).

Indirect Carbon Sequestration

Natural sinks like ocean sequestration as well as terrestrial sequestration (photosynthesis in vegetation on the land) played an important role in carbon management and contribute to 55%–65% anthropogenic CO₂ removal (Scholes *et al.*, 2009).

Carbon Capture by Absorption

Physical absorption

The Physical process of CO₂ absorption is based on Henry's law in which efficient CO₂ absorption is mainly in presence of high pressure and a low temperature, while desorption in reduced pressure and high temperature (Yu *et al.*, 2012). There are many

processes like selexol process; rectisol process, purisol process, morphysorb process, and fluor process are used for physical CO₂ absorption.

Chemical absorption – Amine absorption technology

Chemical absorption of CO₂ into reactive solvents system is regarded as a proven technology to CO₂ mitigation (Norouzbahari *et al.*, 2016) (Tables 6–8).

Fig. 6 Overview of different approaches for Carbon capture process and system.

Fig. 7 CO₂ separation and capture techniques.

Table 6 Direct and indirect carbon sequestration

Carbon sink	Total carbon content (Gt)	Carbon mitigation (Gt/yr)	Nat Carbon sequestration (Gt/yr)	Route return to atmosphere	References

Ionic liquid

Recently, ionic liquids (IL) has attracted widespread attention toward carbon dioxide management due to very low vapor pressure, non toxicity, good thermal stability and high polarity (Yu *et al.*, 2012). Table 9 to provide value of different ILs for peak CO₂ solubility.

* χ_{CO_2} is the solubility of CO₂ (mole fraction).

Table 10 CO₂ adsorption capacities for metal organic frameworks

Carbon Capture by Adsorption

Adsorption of CO₂ capture is considered as one of the potential options for CO₂ management. This approach is mainly dependent on (a) kinetics (adsorption/desorption); (b) CO₂ capacity; (c) adsorption and desorption temperatures (low heat capacity) (d) regenerability and (e) impact of common flue gas components such as H₂O, Hg, SO₂, NO and (f) High CO₂ selectivity (Choi *et al.*, 2009). Adsorption processes involving CO₂ capture by liquid media are widely established even in gas separation via selective adsorption (Yang, 2013).

Inorganic adsorbents

Various physical inorganic adsorbents have been used for CO₂ mitigation process including zeolites, carbonaceous adsorbent, metal oxides materials, microporous and mesoporous materials (activated carbon and carbon sieves), metal organic frameworks (MOFs) and chemically modified mesoporous materials (Ben-Mansour *et al.*, 2016). The adsorption capacities of different adsorbents are summarized in Table 9.

CO₂ adsorption in metal organic frameworks

Carbon dioxide adsorption by metal organic frameworks (MOFs) have emerged as an extensive class of CO₂ capture materials with ultra-high porosity and high internal surface areas attracted much recent attention to their potential applications in gas storage, and selective separation etc. (Zhou *et al.*, 2012).

Chemical adsorbent

Many scientific and industrial works have been devoted to improve selective CO₂ adsorption process and enhancing efficiencies and selectivity by chemical changes and design and development of a suitable adsorbent like synthesizing a high nitrogen content carbon -including adsorbents-by carbonization (Yu *et al.*, 2012). According to the interaction type between basic organic group (amine) and support following types of adsorbent can categorized as, (i) amine (-NH₂) impregnated adsorbent and, (ii) amine (-NH₂) grafted adsorbent (Tables 10–12).

The comparisons of various carbon capture technologies tabulated below (Table 13).

Terrestrial Sequestration

Terrestrial C sequestration is alteration of atmospheric carbon dioxide into biotic and soil C pools. According to Fan *et al.* (1998) presently, the concentrate of C sequestration in forest ecosystems is 1.7 ± 0.5 Pg C yr⁻¹. The forest C is sequestered in lignin and other polymeric C compound by the timber, woody debris, and other woody plants and grasslands (Wofsy, 2001). Afforestation is one of the best options of terrestrial C sequestration (Lamb *et al.*, 2005). As per the IPCC report following carbon sequestration potential like 3 MT C yr⁻¹ in Norway, 6 MT C yr⁻¹ in New Zealand, 9 MT C yr⁻¹ in Sweden, 107 MT C yr⁻¹ in Russia and 117 MT C yr⁻¹ in the USA can lead by only afforestation (IPCC, 2005) (Table 14).

Chemical Carbon Mitigation

The atom of carbon and oxygen in CO₂ molecules are susceptible to nucleophilic and electrophilic attack for substitution reaction of chemical reagents. The various chemical processes and their chemical CO₂ sequestration capacities are shown in Table 15.

Biological Carbon Mitigation

Several biological processes lead to ocean and terrestrial CO₂ sequestration through photosynthesis like phytoplanktonic photosynthesis mechanisms can fix 45 Gt C yr⁻¹. The world ocean currently accounting for a global net uptake of 2.9 Gt C annually of human caused CO₂ emission (Falkowski, 2012). Following biological media involve in biological carbon mitigation.

Microalgae

Microalgal photosynthesis is can lead to potentially long-term sink of carbon through the precipitation of calcium carbonate (Kurano *et al.*, 1995) (Table 16). Microalgae are fast growing can achieved high carbon dioxide fixation rate like 14.6 g cm⁻²/day at 4% CO₂ concentration (Watanabe and Hall, 1996).

Macroalgae

In the coastal areas macroalgae (autotrophic aquatic plants) are the main primary producers with net NPP of 1521 Mt C yr⁻¹ (Duarte *et al.*, 2004). Krause-jensen and Duarte (2016) estimated macroalgae can sequester about 173 Mt C yr⁻¹ globally. Following selected macroalgae strain can use of carbon sequestration purposes (Table 17).

The photosynthetic rate of macroalgae can be used as an indicator of CO₂ capture capacity and can regulated by the enrichment of nutrients, gaseous CO₂ and DIC (Gao and McKinley, 1994). *Enteromorpha compressa* the highest rate of net photosynthetic rate for the green algae range from 400 to 1800 μmol CO₂ g (dry wt)⁻¹ h⁻¹. Similarly *Sargassum muticum* shoes net rates range from 100 to 1670 μmol CO₂ g (dry wt)⁻¹ h⁻¹ (Brown and Tregunna, 1967). The net photosynthetic rate ranges from 250 to 2232 μmol CO₂ g (dry wt)⁻¹ h⁻¹, of *Porphyra* showed highest in the red algae (Smith and Bidwell, 1987). By the adding DIC concentrations (2–10 Mm, pH 8.2) in seawater at the photosynthetic rate of *Porphyra yezoensis* was increased ranges from 1560 to 2230 μmol CO₂ g (dry wt)⁻¹ h⁻¹ and *Gracilaria sp.* increased their photosynthetic rate from 62 to 108 μmol CO₂ g (dry wt)⁻¹ h⁻¹ (Gao *et al.*, 1991).

Cyanobacteria

Cyanobacterias utilize CO₂ as their food source plays important carbon mitigation. Following selected cyanobacterial strains can use direct biological carbon sequestration applications and bio mineralization (Table 18). Cyanobacteria can capture CO₂ by two different modes one via photosynthesis process and Calvin Benson-Bassham process where CO₂ captured and converted into organic compounds and calcium carbonate (Kamennaya *et al.*, 2012).

Cyanobacterial carbonate mineralization have major environmental and geological significance like *Synechococcus sp.* PCC 8806 could mineralise around 2.5 MT carbonate per year over an area of 70 km² (Lee *et al.*, 2004, 2006) and *Nannochloris atomus* can precipitate 1.6 × 10³ T of CaCO₃ in 12 h (Yates and Robbins, 1998). Biological fixation can occur through following six major pathways, (1) Calvin- Benson- Bassham cycle, (2) reductive acetyl-CoA pathway, (3) reductive citric acid pathway, (4) 3-hydroxypropionate/malyl-CoA cycle, (5) 3-hydroxypropionate/4-hydroxybutyrate cycle, and (6) dicarboxylate/4-hydroxybutyrate cycle (Berg *et al.*, 2010).

Table 20 Role of various enzymes in CO₂ sequestration

Enzyme	Function	References
Oxidoreductases	Converting CO ₂ in oxidation state of the carbon element	(Shi <i>et al.</i> , 2015)
Formate dehydrogenase(F _{ate} DH) or carbon dioxide (CO ₂) reductase	Conversion of CO ₂ to formate	(Tishkov and Popov, 2004)
Carbon monodioxide dehydrogenase (CODH). ([NiFe] CO dehydrogenases [NiFe] CODH)	Conversion of CO ₂ to carbon monodioxide (CO)	(Appel <i>et al.</i> , 2013)
Nitrogenase from <i>Azotobacter vinelandii</i> ,	Catalyze the two-electron reduction of CO ₂	(Seefeldt <i>et al.</i> , 1995)
Remodeled nitrogenase	Conversion of CO ₂ to methane	
Lyases	Michael addition (breaking of chemical bonds and generates a new double bond or a new ring structure)	(Shi <i>et al.</i> , 2015)
Carbonic anhydrase (CA)	Conversion of CO ₂ to bicarbonate	(Giri <i>et al.</i> , 2018)
Decarboxylases e.g.,	Conversion of CO ₂ to biodegradable chemicals	(Aresta and Dibenedetto, 2002)
1. 4-hydroxybenzoate decarboxylases from <i>Chlamydomonas reinhardtii</i> AR39, <i>Enterobacter cloacae</i> P240109 and <i>Clostridium hydroxybenzoicum</i>	● Reversible carboxylation of phenol with CO₂ to yield 4-hydroxybenzoate. ● Carboxylation of phenol with CO₂ to synthesize p-hydroxybenzoic acid. ● Catechol carboxylated into 3,4-dihydroxybenzoate in the presence of bicarbonate.	
2. Phenylphosphate enzymes of <i>Thauera aromatica</i>		
3. 3,4-dihydroxy-benzoate decarboxylase from <i>Clostridium hydroxybenzoicum</i>		
F _{ate} DH and methanol dehydrogenase (MDH)	Conversion of CO ₂ to methanol	(Kuwabata <i>et al.</i> , 1994)
Genetically engineered <i>Synechococcus elongatus</i> PCC7942 through the expression of several key genes (<i>alsS</i> , <i>ilvC</i> and <i>ilvD</i>) Rubisco, acetolactate synthase (<i>AlsS</i>), acetohydroxyacid isomeroreductase (<i>IlvC</i>), dihydroxy-acid dehydratase (<i>IlvD</i>) and 2-ketoacid decarboxylase (<i>Kdc</i>)	Produce isobutyraldehyde from CO ₂	(Atsumi <i>et al.</i> , 2009)

Enzymatic Conversion of CO₂

CO₂ fixation/conversion reaction can occur through directly adopting the single enzyme or multiple enzymes (oxidoreductases, synthases or lyases) to catalyze the conversion of CO₂ In vitro or in Vivo.

- (1) *Carbon monodioxide dehydrogenase (CODH)*: Conversion of CO₂ to carbon monoxide by CODH can also lead production of liquid hydrocarbons (Fischer-Tropsch process), acetic acid (Monsanto and Cativa processes), and methanol has received much attention now a days (Woolerton *et al.*, 2010). Two types of CODHs, [NiFe] CO dehydrogenases ([NiFe] CODH) and [MoCu] CO dehydrogenases ([MoCu] CODH) are containing metal subunit [Fe₄S₄Ni] and [MoSCu] active sites (Appel *et al.*, 2013). In nature, the conversion between CO and CO₂ is primarily catalyzed by [NiFe] CO dehydrogenases ([NiFe] CODH) (Parkin *et al.*, 2007).
- (2) *Conversion of CO₂ to Formic Acid/Formate by formate dehydrogenase*: Conversion of CO₂ into formate by the formate dehydrogenase (FDH or FateDH) is also important CO₂ mitigation pathway like *Syntrophobacter fumaroxidans* FDH has also been used to reduce CO₂ and showed very good activity in formate reduction.

- (3) *Conversion of CO₂ to Methanol by dehydrogenases*: Reduction of CO₂ into methanol used as a important material for many industrial and environmental applications. Multi enzyme system is one of the most promising possible routes for the reduction of CO₂ into methanol with following attributes: (1) recycling of the “GHGs” gas, and (2) the production of renewable or sustainable fuel alternatives (Shi *et al.*, 2015). In the multi enzyme system FateDH and methanol dehydrogenase (MDH) as the catalysts for CO₂ reduction with pyrroloquinolinequinone (PQQ) as a cofactor used as electrochemical reduction of CO₂ to methanol (Kuwabata *et al.*, 1994).
- (4) *Conversion of CO₂ by oxidoreductases*: Oxidoreductase transfer of electrons from one molecule to another like conversion of CO₂ by an oxidoreductase and reduce the oxidation state of carbon (Shi *et al.*, 2015).
- (5) *Conversion of CO₂ to Bicarbonate*: Carbonic anhydrase (CA) catalyze CO₂ to bicarbonate (HCO₃[−]) via catalysis with up to 10⁶ per second turnover rate (Lindskog and Coleman, 1973). Single and multienzyme based CO₂ conversion system is given below (Tables 19 and 20).

Conclusion

Carbon mitigation through physical, chemical and biological sequestration from any point sources offers a great potential in the amelioration of GHG mitigation. Carbon dioxide capture and storage (CCS) and sequestration from industrial and energy-related source can consider as an option for stabilization of atmospheric greenhouse gas concentrations. GHG mitigation using biological and chemical methods has many advantages than other conventional mitigation methods like CO₂ is being utilized to produce value added products, chemicals and high value biomass offers a good opportunity for sustainable development in the energy and environmental sectors. Physical adsorption is a good option for carbon dioxide capture at high pressure and low temperature, therefore it is not suitable for high temperature operation like post combustion CO₂ capture. Chemical adsorbent like amine based adsorbent, metal organic frameworks are the suitable under such conditions with high selectivity. Biological carbon mitigation can convert inorganic C to organic C and many advantages like produce high value biomass has a number of applications in cost effective energy production.

Introduction

Indisputably, greenhouse gases emission has been unfavourable to the eco-system (Nabgan *et al.*, 2016). Methane (CH_4) is a reactive trace gas readily available which can be obtained from natural and anthropogenic sources (University of Oxford, 1998). It is the main constituent of natural gas (Zavala-Araiza *et al.*, 2015). CH_4 and carbon dioxide (CO_2) are the main anthropogenic gases present in the atmosphere (Lauder *et al.*, 2013). The increased development of industries and the abundance of non-renewable carbon and H_2 sources have led to the growing reservoir of greenhouse gases. Generally, CH_4 can be transformed into more valuable product such as; syngas (H_2 and CO) using various reforming techniques which include steam, partial oxidation and CO_2 reforming. In fact, CH_4 reforming has become an accepted procedure for producing syngas which is used in the petrochemical industry (Domínguez *et al.*, 2007; Zahedinezhad *et al.*, 2009). Detailed study have been reported using these various techniques viz; steam reforming by Antzara *et al.* (2016), partial oxidation by Jahangiri and Pahlavanzadeh (2012), CO_2 reforming by Foo *et al.* (2012), Osazuwa *et al.* (2017b) and, (Osazuwa and Cheng, 2017). Combination of CH_4 reforming techniques in order to obtain a much improved product have also being reported previously by, Lim *et al.* (2010), Koo *et al.* (2014), (Choudhary and Mondal, 2006). Apart from the fact that the CO_2 reforming of CH_4 reaction consumes greenhouse gases, its products serve as feed for the Fischer-Tropsch synthesis (syngas ratio below 2.0) (Choudhary and Mondal, 2006). The product (H_2) is employed as fuel cells for transmission of clean energy, electricity generation and production systems (Wang *et al.*, 1996; Hosseini and Wahid, 2016). The need to promote a cleaner environment by minimizing global warming cannot be over emphasized. To reiterate this need, over 195 countries signed an agreement in 2015 to take part in a combined attempt to reduce the emission of greenhouse gases. Naturally, CH_4 reforming with CO_2 (greenhouse gases) is an endothermic reaction that occurs at a very slow rate if allowed to progress un-catalysed. Therefore, catalytic reforming of CH_4 with CO_2 is a reaction, which progresses with H_2 and CO formation as products and carbon as unwanted/by products (Pompeo *et al.*, 2009). This carbon deactivates the catalyst; hence, researchers have tried to develop catalysts with improved performance, which minimizes catalyst deactivation from carbon formation on the surface or pore of the catalyst. Noble metal based catalyst was reported to minimize carbon deposition (Hou *et al.*, 2006; Sutthiumporn and Kawi, 2011). However, nickel (Ni) catalyst is more economical (Hirose *et al.*, 2011; Yentekakis *et al.*, 2015). Reports have shown that as a result of the cost of noble metals coupled with the attraction of Ni to carbon, it makes economic sense to enhance the performance of non-noble metal catalyst. Hence, transition metal based catalyst has shown better performance towards syngas production from CH_4 dry reforming (Valderrama *et al.*, 2005; Gallego *et al.*, 2008b; Rivas *et al.*, 2008; Khajeh Talkhoncheh and Haghighi, 2015). Another effective catalyst for CO_2 reforming/ conversion of CH_4 is the perovskite, which requires the introduction of metals into the perovskite matrix. Perovskite possess a structure with superior reduction-oxidation properties that permits very high distribution of metal elements in a reduced system; hence enhancing the activity of the catalyst (Goldwasser *et al.*, 2005b; Moradi *et al.*, 2012). Moreover, the perovskite has a wide selection of A and/or B cations, enabling combinations of varying oxidation state of its elements (Tienthao *et al.*, 2007). Catalytic conversion of greenhouse gases to valuable products can be effectively achieved via CO_2 reforming of CH_4 . However, catalyst inhibition (deactivation) due to carbon formation has been outlined as the major setback that inhibits the revolution of CO_2 reforming of CH_4 to a commercial process. Reports available in literature have attempted to analyse ways to enhance catalyst activity, catalyst stability, reduce carbon formed and deactivation of catalyst by varying supports, promoters and combining metals to obtain support on metal oxides and perovskite type catalysts. Furthermore, various modifications have been carried out to alter the kinetic behaviour of these catalysts in order to improve these aforementioned qualities. This paper seeks to outline the various methods that have been employed in the catalytic conversion of greenhouse gases into valuable products. More specifically, the effects of various catalyst type on the overall behaviour (conversion, yield and kinetic) of greenhouse gases (CH_4 and CO_2) have been emphasized in this review paper.

Greenhouse Gases

Greenhouse effect is a natural (regular) occurrence modelled to retain gases in the earth crust at equilibrium. However, disturbances to the environment take place when imbalance exists. These disturbances are as a result of artificial greenhouse effect which enhances the regular greenhouse effect. Artificial greenhouse effect results from burnt fossil fuels, natural gas, coal and petroleum, while the regular greenhouse effect results from confined heat waves released from the sun. As a result of the heat energy, the temperature of the greenhouse gases in the atmosphere is increased. Activities of man such as; deforestation, burning of fossil fuels, coal, oil, industrialization and population increase are responsible for the excess greenhouse gases produced. Components of greenhouse gases are; water vapour, nitrous oxide, ozone, CH_4 and CO_2 . CO_2 and CH_4 are readily available in much

larger amounts (Lim *et al.*, 2010). The global interest to reduce greenhouse gases has resulted in studies aimed at promoting the mitigation of the two main gases; CH₄ and CO₂ into usable products.

Conversion/Reforming of Methane

CH₄ can be produced naturally and artificially by organic process and man-made activities, respectively. Conversion/Reforming of CH₄ is the separation of its molecules by combining it with the molecules of a splitting agent. CH₄ can be converted via different methods depending on the quality of the product stream required; steam, partial oxidation and CO₂ reforming of CH₄ are amongst the several methods recently reported (Arkatova, 2010).

Steam reforming of CH₄

Already commercialized steam reforming is often used industrially and the process is shown in Eq. 1, (Krylov *et al.*, 1998).

Reforming of CH₄ via steam produces H₂ and CO with ratio of about 3.0. Reports have claimed higher H₂: CO ratio is not ideal for the Fischer Tropsch reaction which produces liquid petrochemicals (Tsipouriari and Verykios, 2001). Low temperature steam reforming of CH₄ using metal oxide (MgO, CaO and La₂O₃) promoted Ni-Ce_{0.8}Zr_{0.2}O₂ catalyst in a compact reformer have been investigated by Kim *et al.* (2017). Results from their study showed that metal oxides improved the basic strength of the catalyst, hence, enhancing the resistance to carbon formation and improving the catalytic activity. Amongst all the catalysts prepared, Ni-La₂O₃-Ce_{0.8}Zr_{0.2}O₂ catalyst had the highest performance as a result of the high dispersion of Ni, strong basicity of La₂O₃ and strong interaction between Ni and La₂O₃. Enhanced catalytic performance of Ni/ α -Al₂O₃ catalyst modified with CaZrO₃ nanoparticles in steam methane reforming have been studied by Lertwittayanon *et al.* (2017). The effects of loading CaZrO₃ nanoparticles (0–15 wt%) were investigated after synthesizing the catalyst using the sequential impregnation method. Results from their study showed that 15 wt% CaZrO₃ nanoparticles provided the highest H₂ yield. The activity was linked to the steam adsorption-dissociation at the sites where O₂ vacancies exist on the surface of CaZrO₃ nanoparticles. Stability of the modified and unmodified catalyst was also tested with the modified Ni/ α -Al₂O₃ catalyst showing higher catalytic performance when compared to the unmodified Ni/ α -Al₂O₃. It was also found that at high S/C ratio of 3.0, excess steam adsorption at the oxygen vacancies on the CaZrO₃ particle occurred resulting in adsorptive competition between steam and CH₄, thereby decreasing CH₄ dissociation. Hence, the optimum S/C ratios for the CaZrO₃-modified Ni/ α -Al₂O₃ catalysts were lower than those for the unmodified Ni/ α -Al₂O₃ catalyst as a result of the very good steam reforming capability of the CaZrO₃ particles.

Partial oxidation reforming of CH₄

In order to produce liquid fuels, syngas ratio less than 2.0 is required (Sutthiumporn and Kawi, 2011; Ruckenstein and Wang, 2002; Khalesi *et al.*, 2008). Syngas with lower ratio are obtained from partial oxidation of CH₄ as shown in Eq. 2 (Goldwasser *et al.*, 2005b).

Kaddeche *et al.* (2017) investigated the partial oxidation of CH₄ on co-precipitated Ni-Mg/Al catalyst modified with copper or iron. The authors used the co-precipitation method to prepare Fe or Cu promoted (Ni/Mg) Al catalysts. The compositional effects of the catalyst and the pre-treatment conditions were tested on the partial oxidation of CH₄. Results from their study revealed that Fe or Cu promoted (Ni/Mg) Al catalysts had high performance in partial oxidation of CH₄. In addition, as the calcination temperature decreased and Ni and Al contents increased, the results showed increasing activity and selectivity towards the products. In all reactions, the catalyst promoted with Fe was superior in terms of the CH₄ oxidation and for the water-gas shift reaction. Adding Cu also enhanced the performance of the (Ni/Mg) Al catalyst. The performance was linked to the creation of NiM (M=Cu or Fe) alloy which enhanced the distribution of Ni particles. LaNiO₃ and La₂NiO₄ supported on CeO₂ were synthesized using a microwave assisted co-precipitation method and the activity test was carried out in the partial oxidation of methane by La Parola *et al.* (2016). Results from their catalytic study showed that at increased temperature (about 800°C), high CH₄ conversion was obtained with approximately 100% CO selectivity. The LaNiO₃CeO₂ stimulated CH₄ cracking with CO/CO₂ evolving in a large temperature span which was in contrast to LaNiO₃ stimulating CH₄ cracking in a more limited range of temperature. This was attributable to the interaction between Ni and Ce, thereby enhancing the catalyst activity in partial oxidation of CH₄ reaction. Partially oxidized CH₄ with bi-functional catalyst I and the formation of Ni^o/La₂O₃ during temperature programmed partial oxidation of methane reaction over LaNiO₃ perovskite have been studied by Nguyen *et al.* (2014). Several characterization techniques such as XRD, TGA, HRTEM/EDX, and FFT were employed to ascertain the physicochemical properties of the catalyst pre, during and post reaction. Oxidation of CH₄ over LaNiO₃ and La₂O₃, and the syngas production over reduced Ni^o/La₂O₃ catalysts were analysed to understand the transformation of LaNiO₃ to Ni^o/La₂O₃ and proposed kinetic model of POM process over final bi-functional Ni^o/La₂O₃.

CO₂ reforming of CH₄

The main challenge of partial oxidation of CH₄ is the exothermicity of the reaction which creates control difficulties during the reaction. Hence, CH₄ dry reforming with H₂: CO ratio less than 2.0 is of higher demand and can be represented by Eq. 3.

Global industrialization has focused attention on the consumption of CO₂. The excessive release of CO₂ has further worsened the critical problems associated with global warming and climate change (Song, 2006). An attractive way atmospheric CO₂ can be effectively minimized is by reforming of CH₄ via CO₂. Catalytic performance of mesoporous carbons modified with lanthanides in dry conversion of methane have been reported by Goscianska *et al.* (2018). Mesoporous carbon was synthesized using SBA-15 and KIT-6 and sucrose as carbon source. After characterization, the catalysts were tested using 1:1 molar ratio of CH₄ and CO₂ at continuous flow in a stainless steel reactor at 650°C under atmospheric influence. From their results, Ce- and La-based catalysts supported on mesoporous carbons showed better activity and stability when compared to the unmodified catalysts supported on SBA-15 and KIT-6. Osazuwa and Cheng (2017) studied the catalytic performance of samarium-cobalt trioxides perovskite catalyst for the conversion of greenhouse gases into cleaner energy. The various outstanding catalytic properties gave way for an excellent conversion (above 90%) in a 30 h experimental setup with the used catalyst showing evidence of carbon deposits. Syngas production via methane dry reforming over neodymium sesquioxide supported Co catalyst prepared using the wet-impregnation technique have been outlined by Ayodele *et al.* (2016a). Their results showed that conversion of both reactants increased with feed ratio and reaction temperature, hence, leading to an increased syngas yield of 59.91% and 62.02% for H₂ and CO, respectively. The authors' proceeded by proposing CH₄ and CO₂ adsorption, activation of CH₄ from CH₄ decomposition and gasification of carbon deposited on the catalyst surface.

Combined steam and CO₂ (dry) reforming of CH₄

Other researchers have attempted to combine steam and dry reforming process to improve the conversion of greenhouse gases and enhance the end product of the reaction. In a study, an ideal design for combining steam reforming with dry CH₄ reforming and reusing CO₂ as raw material have been investigated by Lim *et al.* (2010). In order to minimize cost and energy consumption, steam and dry reforming was combined to reform CH₄ for CO₂ treatment process. Models for the combined process and the steam reforming process were established and the cost was obtained for the overall process. Their results showed that the combined process reduced the net CO₂ by 67% when compared to the steam reforming process. The production of syngas via steam and CO₂ reforming of CH₄ over Ni-Ce/MgAl₂O₄ catalysts with enhanced coke resistance have been investigated by Koo *et al.* (2014). Ni-Ce/MgAl₂O₄ catalyst was prepared using the co-impregnation method by adjusting the Ce/Ni ratio in a range 0.0–1.0. In their study, pre and post catalyst analysis was carried out to determine the effect of Ce addition. It was found that the addition of Ce to Ni/MgAl₂O₄ catalyst affected the NiO crystallite size, metal dispersion and reduction degree. Ni-Ce/MgAl₂O₄ catalyst with Ce/Ni ratio 0.25 had the smallest NiO crystallite size of 8.3 nm and highest metal dispersion of 4.91%. Ni-Ce/MgAl₂O₄ with Ce/Ni ratio of zero had the largest NiO crystallite size of 11.0 nm and lowest metal dispersion of 3.49%. In terms of catalytic activity, Ni-Ce/MgAl₂O₄ (Ce/Ni=0.25) catalyst had the best activity and coke resistance as a result of the improved metal dispersion, better reducibility and higher surface oxygen transfer. Choudhary and Mondal (2006) combined partial oxidation, CO₂ and steam conversion to syngas catalysed by NdCoO₃ perovskite catalyst. The conversion and yield were affected by CO₂/H₂O feed ratio in the CO₂ and steam reforming process. For the CH₄ reforming process via CO₂ and partial oxidation, reactants conversion, H₂ selectivity and the net heat of reaction are affected by operating constraints like relative O₂ concentration in the feed, temperature and space velocity. Interestingly, their report showed no carbon deposit on the catalyst for both cases, thereby placing reduced NdCoO₃ as a very good catalyst for carbon-free CO₂ combined with steam reforming. Interestingly, CO₂ reforming of CH₄ reaction proceeds with side reactions such as the reverse water-gas shift reaction (RWGS) represented in Eq. 4.

The endothermicity of the RWGS coupled with the formation of H₂ and CO (CO₂ reforming of CH₄) is preferred at high temperature. In contrary views, some writers have argued that temperature increase does not favour the conversion of greenhouse gases (forward reaction) because of the negative effects on the catalyst. The resulting effects are catalyst sintering, unsteady behaviour of the catalyst and catalyst active site engulfment by carbon due to increased CH₄ cracking (Luo *et al.*, 2000). In reforming of CH₄ with CO₂, carbon is produced as a by-product of CH₄ cracking and another side reaction known as the Boudouard reaction represented as Eqs. 5 and 6, respectively, (Richardson and Paripatyadar, 1990).

Another group of writers have argued that CH₄ conversion using CO₂ proceeds at elevated temperature in order to crack CH₄ and minimize the Boudouard reaction side reaction effect. At elevated temperature, the reverse Boudouard reaction is favourable and it is shown in Eq. 7.

Hence, carbon formation can be minimized by carefully selecting the reaction operating conditions such as; reaction temperature and type of catalyst.

Catalyst characterization

Catalyst characterization assesses the catalytic physicochemical properties. The need to characterize the catalyst is to ascertain the connection linking the physicochemical properties and the mechanism of reaction and kinetics as a means of developing a suitable catalyst to enhance greenhouse gases conversion. In catalytic studies, some physical characterizations include N_2 physisorption, SEM, FESEM and TEM. Physical properties are the textural properties and morphology of the catalyst. N_2 physisorption which refer to textural properties such as; pore size, surface area, pore size distribution and pore volume are obtained by N_2 adsorption-desorption isotherms data while the morphology of the catalyst is shown by the scanning electron microscopy (SEM), field emission scanning electron microscopy (FESEM) and transmission electron microscopy (TEM). Some chemical characterizations include; EDX, XPS, XRD, NH_3 -TPD, CO_2 -TPD, TGA and FTIR. These chemical characterizations can be sub-divided into elemental (EDX and XPS) and surface chemical analysis (XRD, TPD, TGA, FTIR). Captured images from SEM, FESEM and TEM are analysed by the energy dispersive X-ray (EDX) analyser in order to obtain the catalyst elemental composition. X-ray photoelectron spectroscopy (XPS) is method for elemental and surface analysis due to its increased recognition capability of chemical characteristics without any known damage to the catalyst morphology (Tao *et al.*, 2014). XPS analysis is aimed at obtaining the composition at the surface and binding energy of the catalyst. X-ray diffraction (XRD) pattern of the catalyst shows the crystalline structure of the catalyst. Further computation for the crystalline particle size can be carried out using the Debye-Scherrer equation shown in Eq. 8 (Bradford and Vannice, 1996) or the more precise Williamson–Hall equation represented in Eq. 9 (Khorsand Zak *et al.*, 2011).

$$D_{hkl} = \frac{0.9\lambda}{\beta_{hkl} \cos\theta} \quad (8)$$

$$\beta_{hkl} \cos\theta = \frac{k\lambda}{D_{hkl}} + (4\varepsilon \sin\theta) \quad (9)$$

where λ is the wavelength of Cu-K α , θ is the Bragg diffraction angle, k is a constant (0.9), D_{hkl} is the crystallite size of the catalyst, the peak full width with half maximum (FWHM) is β_{hkl} , and ε is the strain. Data from XRD can be linearized in the Williamson-Hall equation to give the y-intercept (y) and slope (s) represented in Eqs. 10 and 11, respectively.

$$y = \frac{k\lambda}{D_{hkl}} \quad (10)$$

$$s = (4\varepsilon \sin\theta) \quad (11)$$

After purging the surface with gases at high temperature, desorbed molecules from a surface are analysed using a technique known as temperature programmed desorption (TPD). In catalysis, the acidic and basic sites/strength can be determined by the amount of gases adsorbed in the sites. In addition, the catalyst reducibility can be determined by employing H_2 - temperature programmed reduction (H_2 -TPR). Adsorbed H_2 , NH_3 and CO_2 gases on the catalyst surface are estimated using a thermal conductivity detector. The solid state thermal profile prior to calcination is obtained using thermo gravimetric analysis (TGA). Furthermore, post reaction (carbon study), the weight loss profile and the derivative weight loss profiles of the catalyst can also be obtained using the TGA. The TPC uses a flow of N_2 , while the TPO uses O_2 . Using infrared light, the functional groups present in the catalyst can also be identified using the Fourier transform infrared spectroscopy (FTIR). This type of analysis presents the absorbance spectra showing the chemical bonds and molecular structure of the catalyst.

Catalyst Type for Conversion of Greenhouse Gases

Good catalysts are required to stimulate the process of CH_4 dry reforming and improve the product under favourable conditions (Lombardo and Ulla, 1998). At high temperature and under reducing conditions, the formation of syngas is favoured. Hence, several researchers reduce the catalyst with H_2 to aid finely dispersed metal particles of the catalyst (Zhu *et al.*, 2014). In CH_4 reforming reactions, the ability to synthesize a catalyst with high performance is of great interest. Hence, it is desirable to obtain a deactivation free catalyst that can effectively combine greenhouse gases (CH_4 and CO_2) to produce valuable products. Researchers have tried to obtain this kind of catalyst by supporting and promoting the active site of the catalyst (Su *et al.*, 2014). CH_4 cracking during the CO_2 reforming of CH_4 is a major source of carbon. Carbon formation during the reforming process has been the major drawback and it is still under investigation up till date (Sutthiumporn *et al.*, 2012). Noble metals show good performance and more importantly are have less affinity for carbon during methane dry reforming (Hou *et al.*, 2006). The use of noble metals is however to advisable due to their high cost and unavailability. To substitute for noble metals, attention have shifted to Group VII transition metals like Nickel (Ni) (Wang *et al.*, 1996). These type of metals are active and selective towards CH_4 dry reforming (Valderrama *et al.*, 2005; Rivas *et al.*, 2008; Khajeh Talkhonchek and Haghighi, 2015; Pichas *et al.*, 2010). Additionally, the low cost of transition metals is another advantage over noble metals (Yentekakis *et al.*, 2015). In terms of superior activity, an effective catalyst for methane dry reforming is the Ni-based catalyst (Gallego *et al.*, 2008a). However, the active site of Ni-based catalyst are readily attacked by carbon, (Gallego *et al.*, 2008b; Ashcroft *et al.*, 1991). Supported cobalt (Co) catalysts (Ruckenstein and Wang, 2000) and Co-La based perovskite catalyst have also been applied in methane dry reforming (Valderrama *et al.*, 2013). In summary, Ni-based catalyst have shown superior catalytic properties in CO_2 reforming of CH_4 , supported Co catalyst have been reported to exhibit better stability towards the reaction as a result of its superior ability to withstand carbon attacks and extreme

temperature changes (Ferreira-Aparicio and Guerrero-Ruiz, 1998). In addition, Co catalyst have also being reported to show good catalytic properties in methane dry reforming (Budiman *et al.*, 2012).

Supported Metal Catalyst for Conversion of Greenhouse Gases

SBA-15 supported mesoporous Ni and Co catalysts with high coke resistance for CO₂ reforming of CH₄ have been investigated by Erdogan *et al.* (2018). In their study, wet-impregnation method was used to synthesize the mesoporous SBA-15 supported Ni and Co and Ni-Co catalysts. From the activity results, it was found that bimetallic 4Ni-1Co@SBA-15 catalyst had good activity with CH₄ conversion 73% and CO₂ conversion of 89% with reaction temperature of 750°C. Coke formation was decreased when Co was combined with SBA-15 supported Ni catalyst. Durability and activity enhancement of Zirconia supported Ru catalyst for methane dry reforming have been studied by Whang *et al.* (2017). In their study, a small amount of Ru (0.13 wt%) supported on ZrO₂-SiO₂ showed good performance for methane dry reforming reaction carried out at 800°C. Ru size increased (6.3 nm) after Ru was placed on the SiO₂ support. In contrast, the size of Ru reduced to 1.4 nm when Ru was incorporated on the ZrO₂-SiO₂ support. Upon testing in methane dry reforming reaction, the Ru/ZrO₂-SiO₂ catalyst showed no carbon deposit while the filamentous carbon was deposited on the Co-Ru/ZrO₂-SiO₂ catalyst. Nickel catalyst particles incorporated on ceria-zirconia were synthesized by different methods and their catalyst performance were evaluated in methane dry reforming by Wolfbeisser *et al.* (2016). The catalyst which they prepared by surfactant assisted co-precipitation was inactive for methane dry reforming due to the engulfment of Ni particle by ceria-zirconia particles. In terms of the catalytic activity, it was found that the catalyst prepared without surfactant was similar to that of Ni-ZrO₂. Ni-ZrO₂ did not show a better performance when compared to ceria-zirconia supported Ni catalyst even though filamentous carbon was reduced during the reaction. In summary, the authors linked the catalyst activity to the method of preparation and phase composition. The effects of support on the activity of Ni-based catalyst in dry methane reforming have been reported by Zhang *et al.* (2015). It was found that support significantly affected NiO species. According to the authors, SiO₂, TiO₂ and ZrO₂ as support have a weak attraction to NiO. These could lead to catalyst inactivity as a result of accumulation of active metal species. In contrast, Al₂O₃ and MgO showed strong interaction with NiO leading to phase modification of NiAl₂O₄ and NiO-MgO, hence, making the reduction process difficult to attain. Therefore, NiO supported on MgO-modified Al₂O₃ exhibited the best catalytic performance (100 h stability) in methane dry reforming. The effects of phosphorus addition to Rh-supported catalysts for conversion of methane with CO₂ have been studied by Cimino *et al.* (2017). Three types of these catalysts were prepared; (i) dispersed phosphorus and rhodium on La-stabilized γ -Al₂O₃; (ii) stabilizing γ -Al₂O₃ with phosphorus and then dispersing rhodium; (iii) dispersing rhodium on AlPO₄ support and Rh incorporated on La-stabilized γ -Al₂O₃ was used a catalyst reference. It was found that the addition of phosphorus to the supports increased the catalyst acidity and suppressed CO₂ activation leading to reduction in activity and carbon resistance during methane dry reforming reaction.

Promoted Metallic Catalyst for Conversion of Greenhouse Gases

Samaria-doped Ni and Co/SBA-15 catalysts for methane reforming with CO₂ has been reported by Taherian *et al.* (2017). It was found that samaria doped Ni/SBA-15 gave the best CH₄ conversion (about 58% at 700°C). However, samaria-doped Co/SBA-15 has very low conversion of methane (about 25% at 700°C). The author related the effects of samaria on Ni/SBA-15 to reduced NiO particles, increased dispersion of NiO and reduced carbon formation. The undesired influence of samaria on Co/SBA-15 catalyst was as a result of Co oxidation and Co particles sintering at elevated temperatures. Károlyi *et al.* (2018) reported methane dry reforming over Ni-in/SiO₂ catalyst free of carbon deposit. Findings from their study showed that carbon deposit on Ni/SiO₂ can be completely eradicated from the process of greenhouse gases conversion by the addition of indium as promoter to the catalyst. Characterizations such as TPR, CO₂-TPD and XPS suggested the interaction between the two metals. According to their report, indium diluted the nickel surface thereby minimizing the formation of carbon species and carbon nanotubes on the catalyst surface in-situ the conversion of methane with CO₂ reaction. Promotional effect of Gd over Ni/Y₂O₃ catalyst for methane dry reforming have been investigated by Al-Fatesh (2017). The effects of calcination temperatures, activation temperature and time were studied. It was found that a maximum H₂ yield of 82.8% was obtained at calcination temperature of 800°C, activation temperature of 800°C and reaction temperature of 700°C. In order to inhibit carbon formation, the catalyst was promoted by Gd. Interestingly, 1 wt% of Gd altered the carbon formation mechanism and reduced the carbon deposited. This property of Gd was linked to the superior basicity of the Gd when compared with non-promoted Ni/Y₂O₃ catalyst. Dispersed Gd-doped Ni/ZSM-5 catalyst for enhanced carbon-resistant for dry reforming of methane have been reported by Sarkar *et al.* (2016). Adding Gd forms GdNi₅ alloy on the ZSM-5 support with particle size ranged 2–10 nm. It was found that Gd enhanced the mass transfer effects of the reactants and products, respectively, while hindering accumulation of the Ni nanoparticles. According to the authors, Gd releases O₂ to oxidize the carbon deposited on the Ni sites. The Gd promoted Ni/ZSM-5 catalyst was able to withstand 100 h of reaction runs without catalyst deactivation. Interestingly, Ni/ZSM-5 catalyst deactivated during the methane dry reforming reaction due to Ni metal sintering. Ghods *et al.* (2016) studied the effects of alkaline earth promoters on the catalytic performance of Ni catalyst supported on mesoporous magnesium silicate in methane dry reforming reaction. The catalysts were characterized by N₂ adsorption, X-ray diffraction, TPR-TPO techniques. It was found that modifying the catalyst decreased the specific surface area and the distribution of the pore sizes. TPR also showed a decrease in the temperature of reduction of the catalyst. From their results, promoting the catalyst with MgO gave the highest catalytic performance. Ni/MgSiO₃ catalysts modified by different contents of MgO were synthesized and results showed that deposited carbon on the catalyst surface decreased with increase in MgO content.

Perovskite Catalyst for Conversion of Greenhouse Gases

The perovskite is a mineral with the configuration of CaTiO_3 (Zhu *et al.*, 2014). It was named after the Russian mineralogist, Count Lev Aleksevich Von Perovski but was actually discovered by Gustav Rose in 1839 (Screen, 2007). 'A' depicts a rare earth or alkaline earth metal, while 'B' depicts the transition metals in the general formula ABO_3 or A_2BO_4 (Mishra and Prasad, 2014). The perovskite structure is cubical with 'A' cation being 12-fold coordinated and 'B' cation 6 fold coordinated with O_2 anions (Peña and Fierro, 2001; Goldwasser *et al.*, 2003). The framework of the perovskite is a ReO_3 type framework configured by adding 'A' cations to the BO_6 octahedral structure (Peña and Fierro, 2001). Various isomorphous solids can be prepared from the perovskite for catalytic studies. The properties and oxidation states of A and B sites are the basis for the catalytic nature of the perovskite. In catalytic studies, perovskites with higher surface area are desirable; however, other factors have played significantly affected the performance of the catalyst. Furthermore, the method of preparation plays an important role in the physical properties of the perovskite. Perovskites prepared using the solid state synthesis method is a very stable solid at extreme temperatures in catalytic reactions. Nonetheless, this synthesis route fails for perovskite employed in surface related studies but are applied mainly in electronic and electrical applications (Labhasetwar *et al.*, 2015). As catalyst, the stability and activity of the perovskite is controlled by the 'A' cation and 'B' cation, respectively (Mishra and Prasad, 2014; Zhong *et al.*, 1997). In another perspective, Zhang (1990) reported that 'A' metals influences the amount of adsorbed O_2 , while 'B-site' influences the quality of adsorbed O_2 . Peña and Fierro (2001) stated that partially substituting the 'A' site with rare earth cations can alter the structural defects and oxidation state such as ionic vacancies. For the 'B' site partial substitution enhances the structural stability and catalytic performance of the catalyst. This claim was supported by Goldwasser *et al.* (2005a) who also reported that the activity of the catalyst could be enhanced by substituting the A and/or B sites leading to slight crystalline structural changes. About 90% of the metals on the periodic table can be incorporated into the A and/or B ionic sites of the perovskite, hence resulting in different stoichiometry and crystalline shapes (Zhu *et al.*, 2014). The major drawback of the perovskite is it relatively low surface area, therefore researchers have focus attention on ways to improve the surface area of the perovskite (Lombardo and Ulla, 1998). The solid state properties of perovskites has further beamed more search light on the use application of perovskite in catalysis (Lombardo and Ulla, 1998). Very recently, more author are using perovskite as catalyst in methane dry reforming by incorporating rare earth or alkaline earth metal into the 'A' site and a transition metal into the 'B' site (Goldwasser *et al.*, 2005b; Hayakawa *et al.*, 1999). Perovskites meets the requirement to be applied in catalysis for reforming reactions because it provides a platform for its constituent's metals to be stable and well dispersed (Goldwasser *et al.*, 2003; Tomishige *et al.*, 2002). The structure of the perovskite is significant in formulating a catalyst that can resist carbon formation during methane dry reforming. La-Ni based perovskites have been reportedly employed for syngas production from methane dry reforming however, for this type of catalyst, structural differences/defects were often observed post reaction as a result of the carbon deposited which leads to catalyst deactivation (Lombardo and Ulla, 1998; Gallego *et al.*, 2006; Jahangiri *et al.*, 2013; Zheng *et al.*, 2015). Perovskite type oxides $\text{LaFe}_{1-x}\text{Co}_x\text{O}_3$ for chemical looping steam methane reforming to syngas and H_2 production have been investigated by Zhao *et al.* (2016). $\text{LaFe}_{1-x}\text{Co}_x\text{O}_3$ with $x=0.1, 0.3, 0.5, 0.7, 1.0$ were employed as O_2 carriers and in effects of Co on the perovskite characteristics were analysed. It was found that the optimal Co required was 0.3. Although, moderate sintering occurred, $\text{LaFe}_{1-x}\text{Co}_x\text{O}_3$ catalyst was able to regenerate in twenty redox reactions. Syngas ratio of 2.0 was obtained with 85% conversion, 43% of CO selectivity and 50% of H_2 selectivity. In the steam oxidation cycle, H_2 production of approximately 4 mmol g^{-1} O_2 carriers was produced. Dama *et al.* (2018) prepared and investigated alkaline earth metal substituted perovskite catalyst for methane dry reforming. From characterizations carried out, it was found that the perovskite A site was responsible for the structure, basicity, O_2 deficiency and Ni dispersion. Results showed that calcium promoted perovskite ($\text{CaZr}_{0.8}\text{Ni}_{0.2}\text{O}_{3-\delta}$) showed better CH_4 and CO_2 conversion rate with stability maintained even after 500 h of reaction. In terms of carbon formation, their studies revealed that the type of carbon formed depends on the basicity of the perovskite, metal to support interaction, Ni crystallite size, surface hydroxyl groups and O_2 defects. In summary, the authors successfully proved that $\text{CaZr}_{0.8}\text{Ni}_{0.2}\text{O}_{3-\delta}$ was a very good catalyst for methane dry reforming in terms of its activity and stability. The effects of incorporation of perovskite type oxides into a mesoporous SBA-15 silica support in methane dry reforming have been reported by Rivas *et al.* (2010). It was found that incorporating the perovskite into the SBA-15 mesoporous silica increases reactants conversion and selectivity for syngas production but a decrease in reactants conversion were observed when another cation was added to the perovskite active site. A comparative study on methane dry reforming on LaNiO_3 perovskite catalysts supported on mesoporous SBA-15, MCM-41 and silica carrier have been studied by Wang *et al.* (2013). It was found that the pore structure had a direct impact on the catalyst activity and stability. More specifically, $\text{LaNiO}_3/\text{MCM-41}$ had higher activity due to more uniformly dispersed Ni particles in the catalyst. $\text{LaNiO}_3/\text{SBA-15}$ showed better stability when compared with $\text{LaNiO}_3/\text{MCM-41}$ as a result of the stable silica structure which resisted the accumulation of Ni particles. Furthermore, it was reported that the hexagonal matrix of $\text{LaNiO}_3/\text{SBA-15}$ was retained even after reaction unlike the $\text{LaNiO}_3/\text{MCM-41}$ matrix which was completely modified resulting in metal agglomeration.

Catalyst Deactivation in the Conversion of Greenhouse Gases

Efforts have being put in place to enhance the catalyst for conversion of greenhouse gases (CO_2 and CH_4) particularly, for Ni-based catalyst so as to minimize catalyst deactivation due to carbon attacks. In methane dry reforming, catalyst deactivation are triggered by carbon formation which causes reactor pressure build up, carbon attack on metal site and agglomeration of the active metal, thereby reducing and eventually blocking the catalyst pores. Several combinations of La-Ni-Co have been used as catalyst by Yang *et al.* (2013), González *et al.* (2005) and Valderrama *et al.* (2010) try to minimize catalyst deactivation during the conversion of greenhouse gases (CO_2 and CH_4). Due to the increased rate of carbon formation when using transition metals especially Ni catalyst in CO_2 reforming of CH_4 , rare earth metal

oxide rich in lattice O_2 such as CeO_2 , La_2O_3 , TiO_2 and SiO_2 or mixed supported oxide such as ZrO_2-SiO_2 , $La_2O_3-SiO_2$, (Sutthiumporn and Kawi, 2011; Ayodele *et al.*, 2016b), can be used as support for the metallic catalyst. The carbon deposited is gasified by Lattice O_2 released by this oxides, hence, purging the metallic active surface. Recently, researchers have focused attention not only on producing an efficient catalyst but also to reducing carbon deposit on the catalyst surface in the course of the CH_4 reforming reaction. An efficient means of merging transition metals and rare earth oxides is by hosting the metals in the perovskite structure (Moradi *et al.*, 2014). Studies have shown that the superior solid-state properties of the perovskite have presented this type of catalyst as a very good candidate for methane dry reforming (Lombardo and Ulla, 1998). The performance of cobalt aluminate as an O_2 rich catalyst for methane dry reforming have been reported by Wong *et al.* (2017). The catalyst was synthesized via sol-gel method as an O_2 carrier which inhibits the carbon formation rate. Employing this catalyst, the authors successfully obtained a novel mechanism for syngas production via the catalyst reduction by CH_4 and regeneration with CO_2 . They conducted a stability test using the best cobalt aluminate catalyst with 33.33% of Co content. It was found that the catalyst was stable for up to 30 h with 97.2% and 99.7% H_2 and CO yield, respectively with only 1.9% CH_4 converted to carbon. Re-alloy catalysts with improved stability in CO_2 reforming of CH_4 reactions have been investigated by Zubenko *et al.* (2017) Perovskite precursors ($LaFeO_3$) were promoted with Ni and Re. Reducing the perovskite catalyst ex-solved Re-alloy nanoparticles which showed good performance in methane dry reforming. The authors carried out a 70 h reaction study with no carbon deposits or metal particle sintering. Son *et al.* (2014) studied coke formation over $Ni/\gamma-Al_2O_3$, Co- $Ni/\gamma-Al_2O_3$ and Mg-Co- $Ni/\gamma-Al_2O_3$ catalysts for CO_2 reforming of CH_4 . The effects of promoting the catalyst with Mg and Co have been analysed to know the value on coke deposits. Amongst all the catalyst employed for the study, Mg-Co-Ni/ $\gamma-Al_2O_3$ catalyst had the highest performance with CH_4 conversion over 95% for 200 h and minimal coke formation. The increased activity resulted from the addition of Mg and Co which enhanced the cracking of CH_4 and dissociation of CO_2 . High carbon-resistance $Ni/CeAlO_3-Al_2O_3$ catalyst for CH_4/CO_2 reforming was investigated by Chen *et al.* (2013). After reduction at $900^\circ C$, $CeAlO_3$ phase was formed. In their study, it was found that the catalyst showed good activity with or without $CeAlO_3$ for 250 h at $800^\circ C$ and WHSV of $20,000\text{ mLh}^{-1}\text{gcat}^{-1}$. However, as the $CeAlO_3$ phase increased, carbon formation progressively dropped from 0.92 to 0.29 gcat^{-1} . They concluded that $CeAlO_3$ can minimize the formation of graphitic carbon on the metallic surface with the formation of amorphous carbon being independent of the $CeAlO_3$ phase. This phase ($CeAlO_3$) was also responsible for breaking down CO_2 to release O_2 species which aided gasification. Carbon gasification from Fe-Ni catalyst supported on $MgAl_2O_4$ after methane dry reforming was reported by Theofanidis *et al.* (2016). Gasification was obtained using a transient response technique known as temporal analysis of products (TAP). After the reaction, graphitic and amorphous carbons were formed. The oxidation of CO_2 removed some of the carbon species located in the active metal sites. The carbon species removal involves: (1) CO_2 dissociation on the Ni site closely followed by carbon oxidation by surface O_2 . (2) CO_2 oxidation by Fe and carbon oxidation by the lattice O_2 from Fe oxide. The carbon species oxidation by O_2 which was observed in the TPO analysis and the isothermal test included two steps: (1) Surface carbon oxidation by lattice O_2 and (2) the movement of particles to the carbon species deposited away from the active metallic sites followed by the lattice O_2 oxidation of Fe and /or NiO.

Kinetics of conversion of greenhouse gases (methane dry reforming reaction)

The kinetics and mechanism of syngas production from the mitigation of CH_4 using CO_2 over $SmCoO_3$ perovskite catalyst operated in the temperature ranged 973–1073 K was investigated by Osazuwa *et al.* (2017a). The authors carried out detailed study of the mechanism of the reaction and postulated a model for the process. The reaction mechanism predicts CH_4 adsorption on the Co° , CH_4 decomposition and carbon formation. They reported that the mechanism also predicted the formation of $Sm_2O_2CO_3$ which reacted with carbon to form CO.

Conclusions

Various methods exist for the conversion of greenhouse gases to more valuable products. Amongst these methods are the steam reforming, partial oxidation and CO_2 reforming of CH_4 . In terms of the amount of greenhouse gases converted (CO_2 and CH_4) and the usefulness of its products (syngas) in the formation of other petrochemicals, CO_2 reforming of CH_4 is more advantageous. In order to increase this conversion, various support have been used, promoters have been added, bi-metallic catalyst have been developed and even recently perovskite have been employed to mitigate greenhouse gases in various reforming processes. Decomposition of CH_4 on the metallic surface, dissociation of CO_2 on the support, the reduction-oxidation perovskite mechanism coupled with the effects of dopants in inhibiting carbon formation on the surface of the catalyst by introducing O_2 species describes the reaction mechanism. Comparing supported catalyst, with particular interest on Ni-based and Co-based supported catalyst, reports show that perovskite oxides show greater superiority in preventing catalyst deactivation during the conversion of greenhouse gases (CH_4 and CO_2) as a result of the abundance of O_2 species in its structure.

Challenges of Employing Renewable Energy for Reducing Greenhouse Gases (GHGs) and Carbon Footprint

Chandan K Chanda and Dipanjan Bose, Indian Institute of Engineering Science and Technology, Shibpur, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

The responsibility of the reduction of the greenhouse gas emissions lies largely with the industrialized world, though the developing countries are likely to be the source of an increasing proportion of future emissions. The projected climate change under various scenarios is likely to have implications on food production, water supply, coastal settlements, forest ecosystems, health, energy security etc. The survey says that the global mean temperature may increase between 1.4 and 5.8°C by 2100. This unprecedented increase is expected to have severe impacts on the global hydrological system, ecosystems, sea level, crop production and related processes. The impact would be particularly severe in the tropical areas, which mainly consist of developing countries, including India. All the Developing country was not be able to adopt any strategy because it is more concerned to the social economic development. Various sustainable methods and renewable technologies which will be accepted environmentally and globally too. Other than talking about socio economic growth, concentration must be dissipated to the introduction of the green technology into the development of the sustainable technologies for the prevailing problem of the Climate change impact. This work captures and disseminates the impacts and perspectives on climate change from the Global context. Climate change could represent an additional stress on ecological and socioeconomic systems that are already facing tremendous pressures due to rapid urbanization, industrialization and economic development. While talks about the reduction of GHG's between various industrialized countries have not yielded the expected, measures are on the run to put a knot for the problem of Climate Change. Now it is our one of the major responsibilities for cutting down the CO₂ and GHG's emissions. Many Environmental Activists have volunteered to bring out a Green Revolution in the industrialized world. The GHGs and carbon footprint has its adversities in food production, water supply, coastal settlements, forest ecosystems, health, energy security etc. The climatic change is a global concern, but the pressure is upon us as its impact upon us is severe. It's now time to mitigate the impacts of the GHGs and Carbon footprint upon our planet. The livelihood of vast population depends on climate-sensitive economic sectors like agriculture, forestry and fisheries. The costs of not addressing climate change or to adapt to it are very uncertain, but their welfare consequences are enormous. Adaptation is a private or local public good, whereas mitigation is a global public good. The individuals or communities bear the risk wherever there is undersupply of adaptation measures. Adaptation costs are the insurance payments and the costs of not addressing adaptation are the damages from unmitigated climate risks. There are many ways to pursue sustainable development strategies that contribute to mitigation of GHGs and Carbon footprint. So our responsibility is to find a suitable sustainable strategy.

Aspects of Renewable Technology

Renewable technology is a technology that is environment-friendly and ensures that natural resources are conserved. Green technology is the future at large, and the main aim of this innovative technology is to avoid any deterioration to the environmental resources. In a way, green technology helps in reducing the amount of pollution that is being emitted during the process of production and even while consuming the products. It talks about the relationship between human beings and natural resources, and the irreversible hazard that is being caused to the nature and the environment because of the economic activities. One can quote some examples of environmental hazards such as pollution of rivers, global warming resulting in depletion of ozone layer etc.

Both the production and consumption are so massive that one can witness the tremendous amount of damage that is being caused to the environment and natural resources every second. If the trend continues, then one day we may have to zero in on what we have achieved and get into the shoes to rectify our unpardonable mistakes, which are irreparable. Reusable technology is not only essential for sustainable development in the long-run but there are also short-term advantages of using eco-friendly fuels. There are certain crucial issues that need to be focused upon while introducing green technology. For instance, a social awareness about the need for environment-friendly goods and services for production and consumption at a larger scale is required. And, for this, a massive campaign on this issue has to be undertaken. Renewable technology as a subject need to be made mandatory in academics. The industrial segment needs to be pushed forward to come out with more environment-friendly production and consumption processes. Various incentives need to be given to the industrial sector, which is ready to innovate and implement green technology.

Renewable Technology Sources and it's CO₂ Emissions

Here renewable energy sources like hydro, wind, photovoltaic, fuel cell, biomass, ocean thermal energy and geothermal energy sources are considered as eco-friendly technology or green technology ([Table 1](#)).

Table 1 Different renewable technologies and their emissions

Renewable technology	Basic information	Renewable sources ^a	CO ₂ emission ^b (gmCO ₂ eq/kWh)
Fuel cell	Device which converts chemical energy into electrical energy	Methanol (CH ₃ OH), Natural gas, Reforming of CH ₄ to H ₂ leads to decreased efficiency	50
Photovoltaic (Solar PV)	Generates no heat and produces electricity from solar radiation	Sun	Utility scale – 48 Rooftop – 41
Wind	Converts wind energy to electrical energy by wind-turbines.	Wind	Offshore – 12 Onshore – 11
Hydro	Natural Resource of River water	Water	24
Biomass	Biofuel, Waste management system	Biological waste	Dedicated – 230
Geothermal energy	Thermal energy of Earth	Earth Temperature	38
Other renewables	OTEC (Ocean thermal energy conversions)	Temperature difference between cooled water and warm tropical surface waters	17

Greenhouse Gases

The greenhouse effect is the process by which absorption and emission of infrared radiation by gases in a planet's atmosphere warm its lower atmosphere and surface. It was proposed by Joseph Fourier in 1824, discovered in 1860 by John Tyndall.

On Earth, an atmosphere containing naturally occurring amounts of greenhouse gases causes air temperature near the surface to be warmer by about 33°C (59°F) than it would be in their absence. Without the Earth's atmosphere, the Earth's average temperature would be well below the freezing temperature of water. The major greenhouse gases are water vapor, which causes about 36%–70% of the greenhouse effect; carbon dioxide (CO₂), which causes 9%–26%; methane (CH₄), which causes 4%–9%; and ozone (O₃), which causes 3%–7% (Fig. 1).

Human activity since the Industrial Revolution has increased the amount of greenhouse gases in the atmosphere, leading to increased radiative forcing from CO₂, methane, tropospheric ozone, CFCs, and nitrous oxide. According to work published in 2007, the concentrations of CO₂ and methane had increased by 36% and 148% respectively since 1750. These levels are much higher than at any time during the last 800,000 years, the period for which reliable data has been extracted from ice cores. Less direct geological evidence indicates that CO₂ values higher than this were last seen about 20 million years ago.

Fossil fuel burning has produced about three-quarters of the increase in CO₂ from human activity over the past 20 years. The rest of this increase is caused mostly by changes in land-use, particularly deforestation. Another significant non-fuel source of anthropogenic CO₂ emission is the calcination of limestone for clinker production, a chemical process which releases CO₂. There are efforts to develop types of cement that produce less CO₂ but it is feared not enough is being done. Estimates of global CO₂ emissions in 2011 from fossil fuel combustion, including cement production and gas flaring, was 34.8 billion tones (9.5 ± 0.5 PgC), an increase of 54% above emissions in 1990. Coal burning was responsible for 43% of the total emissions, oil 34%, gas 18%, cement 4.9% and gas flaring 0.7% (Fig. 2).

In May 2013, it was reported that readings for CO₂ taken at the world's primary benchmark site in Mauna Loa surpassed 400 ppm. According to professor Brian Hoskins, this is likely the first time CO₂ levels have been this high for about 4.5 million years. Monthly global CO₂ concentrations exceeded 400 ppm in March 2015, probably for the first time in several million years. According to the global carbon project, carbon emission rates plateaued from 2014 to 2016, rose by 1.6% in 2017, then rose again by 2.7% in 2018.

Over the last three decades of the twentieth century, gross domestic product per capita and population growth were the main drivers of increases in greenhouse gas emissions. CO₂ emissions are continuing to rise due to the burning of fossil fuels and land-use change. Emissions can be attributed to different regions. Attributions of emissions due to land-use change are subject to considerable uncertainty.

Emissions scenarios, estimates of changes in future emission levels of greenhouse gases, have been projected that depend upon uncertain economic, sociological, technological, and natural developments. In most scenarios, emissions continue to rise over the century, while in a few, emissions are reduced. Fossil fuel reserves are abundant, and will not limit carbon emissions in the 21st century. Emission scenarios, combined with modeling of the carbon cycle, have been used to produce estimates of how atmospheric concentrations of greenhouse gases might change in the future.

In this given Fig. 3 is a simplified, schematic representation of the flows of energy between space, the atmosphere, and the Earth's surface, and shows how these flows combine to trap heat near the surface and create the greenhouse effect. Energy exchanges are expressed in watts per square meter (W/m²). If this is not feasible due to space limitations it should possibly be explained in the image notes that the remaining grey part of the arrow stands for thermic energy transmission by convection of

Greenhouse gas emissions

Contribution to cumulative emission reduction, 2010 – 2050

— History
 — Trend scenario
 ● Goal

↓ Policy gap

A Avoid deforestation
B Reduce other greenhouse gases
C Reduce other energy-related emissions
D Increase nuclear power
E Increase bio-energy
F Increase solar and wind power
G Increase CO₂ capture and storage
H Improve energy efficiency

Fig. 1 The graph on the top shows three “pathways” to meet the UNFCCC’s 2°C target, labelled “global technology”, “decentralized solutions”, and “consumption change”. Each pathway shows how various measures (e.g., improved energy efficiency, increased use of renewable energy) could contribute to emissions reductions. *Source:* PBL Netherlands Environmental Assessment Agency.

sensible and latent heat. The sun is responsible for virtually all energy that reaches the Earth’s surface. Direct overhead sunlight at the top of the atmosphere provides 1366 W/m²; however, geometric effects and reflective surfaces limit the light which is absorbed at the typical location to an annual average of ~235 W/m². If this were the total heat received at the surface, then, neglecting changes in albedo, the Earth’s surface would be expected to have an average temperature of –18°C. Of the surface heat captured by the atmosphere, more than 75% can be attributed to the action of greenhouse gases that absorb thermal radiation emitted by the Earth’s surface. The atmosphere in turn transfers the energy it receives both into space (38%) and back to the Earth’s surface (62%), where the amount transferred in each direction depends on the thermal and density structure of the atmosphere. This process by which energy is recycled in the atmosphere to warm the Earth’s surface is known as the greenhouse effect and is an essential piece of Earth’s climate. Under stable conditions, the total amount of energy entering the system from solar radiation will exactly balance the amount being radiated into space, thus allowing the Earth to maintain a constant average temperature over time. However, recent measurements indicate that the Earth is presently absorbing 0.85 ± 0.15 W/m² more than it emits into space. An overwhelming majority of climate scientists believe that this asymmetry in the flow of energy has been significantly increased by human emissions of greenhouse gases. This figure was created by Robert A. Rohde from published data and is part of the Global Warming Art project.

Carbon Footprints

A carbon footprint is historically defined as the total emissions caused by an individual, event, organization, or product, expressed as carbon dioxide equivalent.

In most cases, the total carbon footprint cannot be exactly calculated because of inadequate knowledge of and data about the complex interactions between contributing processes, including the influence of natural processes that store or release carbon dioxide. For this reason, Wright, Kemp, and Williams, have suggested to define the carbon footprint as:

"A measure of the total amount of carbon dioxide (CO_2) and methane (CH_4) emissions of a defined population, system or activity, considering all relevant sources, sinks and storage within the spatial and temporal boundary of the population, system or activity of interest. Calculated as carbon dioxide equivalent using the relevant 100-year global warming potential (GWP100)".

Greenhouse gases (GHGs) can be emitted through land clearance and the production and consumption of food, fuels, manufactured goods, materials, wood, roads, buildings, transportation and other services. For simplicity of reporting, it is often expressed in terms of the amount of carbon dioxide, or its equivalent of other GHGs, emitted (**Fig. 4**).

Fig. 4 Global carbon dioxide (CO₂) emissions by countries in 2015.

Most of the carbon footprint emissions for the average household come from “indirect” sources, e.g., fuel burned to produce goods far away from the final consumer. These are distinguished from emissions which come from burning fuel directly in one’s car or stove, commonly referred to as “direct” sources of the consumer’s carbon footprint.

The concept name of the carbon footprint originates from ecological footprint, discussion, which was developed by William E. Rees and Mathis Wackernagel in the 1990s. This accounting approach compares how much people demand compared to what the planet can renew. This allows to assess the number of “earths” that would be required if everyone on the planet consumed resources at the same level as the person calculating their ecological footprint. The carbon Footprint is one part of the ecological footprint. Carbon footprints are more focused than ecological footprints since they measure merely emissions of gases that cause climate change into the atmosphere.

Environmental Pollution

Pollution is the inclusion of several contaminants to the environment causing adverse effects on nature.

Pollution may cause due to natural phenomenon or by foreign particles. It may even be fatal to the life. Death rates are in increasing order for pollution. Presence of greenhouse gases abruptly changing the temperature, climate as well as causes the Global Warming, which is a threat to the society.

Various aspects of environmental pollution are discussed below:

- *Air pollution*: the release of chemicals and particulates into the atmosphere. Common gaseous pollutants include carbon monoxide (CO), sulfur dioxide (SO₂), chlorofluorocarbons (CFCs) and nitrogen oxides produced by industry and motor vehicles. Photochemical ozone and smog are created as nitrogen oxides and hydrocarbons react to sunlight. Particulate matter, or fine dust is characterized by their micrometer size PM10 to PM2.5. Increase of Greenhouse gases.
- *Light pollution*: includes light trespass, over-illumination and astronomical interference.
- *Littering*: the criminal throwing of inappropriate man-made objects, unremoved, onto public and private properties.
- *Noise pollution*: which encompasses roadway noise, aircraft noise, industrial noise as well as high-intensity sonar.
- *Plastic pollution*: It involves the accumulation of plastic products and microplastics in the environment that adversely affects wildlife, wildlife habitat, or humans.
- *Soil pollution*: Soil contamination occurs when chemicals are released by spill or underground leakage. Among the most significant soil contaminants are hydrocarbons, heavy metals, pesticides and chlorinated hydrocarbons.
- *Radioactive pollution*: Radioactive contamination, resulting from 20th century activities in atomic physics, such as nuclear power generation and nuclear weapons research, manufacture and deployment. (See alpha emitters and actinides in the environment).
- *Thermal pollution*: It is a temperature change in natural water bodies caused by human influence, such as use of water as coolant in a power plant.
- *Visual pollution*: In which we can refer to the presence of overhead power lines, motorway billboards, scarred landforms (as from strip mining), open storage of trash, municipal solid waste or space debris.
- *Water pollution*: By the discharge of wastewater from commercial and industrial waste (intentionally or through spills) into surface waters; discharges of untreated domestic sewage, and chemical contaminants, such as chlorine, from treated sewage; release of waste and contaminants into surface runoff flowing to surface waters (including urban runoff and agricultural runoff, which may contain chemical fertilizers and pesticides; also including human feces from open defecation – still a major problem in many developing countries); groundwater pollution from waste disposal and leaching into the ground, including from pit latrines and septic tanks; eutrophication and littering.

Air Pollution

Air pollution is caused whenever concentration of certain detrimental elements increases in the atmosphere to very high level. Air pollution causes objectionable effect on living beings, thereby disturbing natural eco-balance in a significant amount. These

elements can be at any state i.e., solid, liquid or gas. Mostly human related anthropogenic activities such as burning of fossil fuel are responsible for their origin.

Whenever polluting substances are released into the atmosphere, these are transported to the atmosphere. Some of these substances chemically react with other constituents in the atmosphere directly in the presence of sunlight while others are transformed to different substances.

Pollutants which are emitted directly to the atmosphere are termed as primary pollutant while pollutants formed in the atmosphere as a result of transformation are called secondary pollutants.

Source of Air Pollution

Air pollution sources can be of three types. These are discussed below

Point Source

A point source for air pollution is a single entity having one or more than one emission points. A coal-based thermal power plant is a good example of point source.

Area Source

Area source for air pollution is a group of smaller sources confined within a particular geographical area. As an example, it can be stated that emissions from kitchens in a residential zone is treated as a collective source for air pollution. Hence it can be termed as an area source.

Line Source

Line source for air pollution is one-dimensional by nature. A roadway is a good example of line source for air pollution.

It is imperative from the above discussion that emission rates for larger and specific point sources can be directly measured by inserting sampling probes to the concerned chimney or vent. However, this will be a troublesome job for determining pollution from area source. This is because it is always not possible to monitor individual emission in a large area source. To tackle this situation the concept of emission factors plays a vital role. Emission factor is a statistical average or the quantitative estimate of the amount of a particular pollutant emitted from a specific source. Basically, the function of emission factor is to measure total emission from similar sources or on stoichiometric calculations. Once, emission factor is determined for a particular sector of area source, then it is multiplied with the number of sources to estimate the total emission in that particular zone.

Propagation and Transformation of Air Pollution

After emission from sources, air pollutants may be transformed to other substances or may be propagated to the atmosphere depending on the atmospheric stability of the particular pollutant. Again, the stability of a particular pollutant depends on various parameters such as the presence of cloud, fog, precipitation, solubility of the pollutant etc.

Atmospheric stability of a particular pollutant depends on its atmospheric residence time. It has been observed that atmospheric mean residence time for pollutants like NO_x , SO_x etc., is less than a day. Hence, their critical environmental impact usually lies within the close vicinity of the source of emission. So, it can be stated that pollution caused by these sources is a local phenomenon.

Pollutants like CO , CO_2 , CH_4 , N_2O , CFC etc., possesses relatively longer mean residence time and hence they accumulate in the atmosphere uniformly throughout the globe. So, pollution caused by these agents is a global phenomenon.

We often encounter a term 'receptor' while discussing about environmental pollution. A receptor is an entity such as a living being or the whole ecosystem affected by the emission of these pollutants.

Air Pollutants

Oxides of Nitrogen (NO_x)

Any kind of combustion is the main source for various oxides of nitrogen. NO_x can be either fuel NO_x or thermal NO_x . The former is produced during a fuel having nitrogen as a constituent while the latter is produced when temperature for combustion exceeds 1500°C . In this high temperature NO_x is produced as a result of chemical reaction between the atmospheric nitrogen with oxygen. It can form nitric acid by chemical reaction with water vapor present in the atmosphere thereby causing acid rain. NO_x is also responsible for photochemical smog.

Oxides of Sulfur (SO_x)

Main source for sulfur emission is fossil fuel-especially coal. Most of the SO_x emitted in atmosphere is SO₂. A little portion is SO₃ which forms sulfuric acid in presence of water vapor. SO_x is a severe polluting agent causing respiratory problem and causes acid rain along with NO_x.

Particulate Matter PM

Particulate matters are tiny, finely divided solid and liquid particles dispersed in air (aerosols). Concentration of PM in atmosphere is measured through an indicator termed as PM₁₀. It indicates particulate matters of diameter of 10 μm or even smaller than that. The standard of 10 μm was chosen due to the fact that 50% of the particles having diameter equal or less than 10 μm deposits over respiratory tract during breathing. Deposition fraction decreases with increase in the diameter of the particulate matter.

Pollution Measuring Indicators

Environmental pollution is caused by emission from mainly human related activities. This type of emission contributes several polluting agents in the atmosphere. Air pollution can be measured either by concentration measurement or by load measurement. Concentration measurement is basically instantaneous in nature whereas load measurement is carried out over a specified time period.

As an example, it can be stated that, if a measurement technique reports that in a certain emission, the amount of SO₂ is 850 mg/m³. This kind of measurement is known as concentration measurement as discussed.

On the other hand, load measurement can be framed over a certain year such as per year basis. This can be further explained with a simple example. Let us consider the case of a coal based thermal power plant. In such measurement, firstly the emission factor for a particular pollutant is multiplied to obtain total emission of the particular pollutant on unit mass basis. Total pollution over a year can be estimated from total generation of the plant in that particular year.

Global Warming

It is the process through which solar energy is entrapped in earth. Global warming is actually the increase in average temperature of earth due to various natural or human related activities. It is well known fact that the source of energy for earth is the sun. Incoming solar radiation coming in the form of visible light penetrates the atmosphere which consists of greenhouse gases (GHG: which is water vapor, carbon dioxide, methane, chlorofluorocarbon etc.) along with other gases such as nitrogen, oxygen etc., after penetrating the atmosphere, the visible solar radiation reaches earth's surface where it delivers a certain amount of energy contained within it and then reemitted to the atmosphere. As a result of this change in energy level, the wavelength of this reemitted wave is increased so that it becomes infrared radiation (IR). GHG present in the atmosphere are opaque to this infrared radiation and hence the reemitted wave is entrapped within earth. This phenomenon is known as greenhouse effect. As a result of greenhouse effect, more and more amount of infrared is entrapped within earth thereby increasing the average temperature of earth which is more pronounced as global warming.

From the above discussion one may think that greenhouse effect is a harmful phenomenon. On the contrary it must be mentioned that, if greenhouse effect did not occur, then average temperature of earth would have been -23°C. So, global warming is responsible for maintaining a suitable average temperature around 15°C for existence of life in this planet. However, the concern is that average temperature is increasing in an uncontrolled fashion due to pollution. The main reason of this is increase in concentration of greenhouse gases (mainly CO₂) due to various anthropogenic activities. The detrimental effects of global warming involve change in rainfall pattern, increase in severity of storms, different unexpected nature of natural calamity in several places, migration and somewhere extinction of several species and ecosystems, flooding in many coastal regions due to thermal expansion of the oceans, melting of glaciers and polar ice etc. Hence, concern has to be grown in this aspect and proper measures should be taken to tackle this menace.

A Case Study: Recent Natural Disasters in India

Recently, India has suffered a number of natural calamities which includes severe thunderstorms in Rajasthan and Uttar Pradesh as well as devastating flood in Kerala. Somehow, the pollution is responsible to accelerate the above-mentioned concerns.

The phenomenon occurs when a sudden downpour proves so heavy that the underlying ground cannot cope with the sheer amount of water it is exposed to and becomes saturated before it has a chance to drain away. Common in low-lying areas, flash floods can also be caused by an intense concentration of rain from thunderstorms on dry soil, unaccustomed to ready absorption. Just six hours of rainfall can be enough to overwhelm the earth.

In built up areas, this can mean sewers overflow and the streets gush like rivers, ferrying debris and in extreme cases running with enough water to lift and carry away cars.

Ordinarily, the flooding of rivers is a very gradual process as it takes time for enough rainfall to percolate through the ground and cause the water level to rise sufficiently so that it overflows before reaching the sea.

Flash flooding, however, gives no such warning.

In the case of Kerala, the weather is part of the four-month monsoon rainy season that strikes the Indian subcontinent every summer.

Local officials have been blamed for exacerbating the situation by failing to gradually open the dams dotting the state's complex river network, waiting instead until they were already full before unleashing the excess water.

Air pollution particles lead to change in the physical properties of monsoon clouds, which can lead to more intense rainfall, flash floods and unusual gaps in the progression of monsoon rainfall, say scientists from Indian Institute of Technology (IIT), Kanpur, who have used long-term satellite data (2002–2016) and modeling to understand the association between aerosols and cloud properties. Their findings are published in the journal, *Nature*.

The thunderstorm in Rajasthan and Uttar Pradesh that killed more than a 100 people in May and the spate of severe thunderstorms this summer may be attributable to such aerosol-induced changes.

Aerosols, particularly black carbon and dust particles, induce "cloud invigoration", which means cloud cover and thickness increases because of reduction in the size of cloud droplets and other structural modifications during cloud formation.

Enhanced cloudiness reflects more sunlight back to space, leading to a cooling effect of the clouds' surface. The enhanced cloud cover limits reflection of solar energy back to space and traps the energy emitted from the surface at night and decreases the surface diurnal temperature range to make days cooler and nights warmer.

It has been observed that the main sources of aerosols are fossil and bio-fuels combustion from residential and industrial sector, biomass burning and forest fires.

India's Stance on GHG and its Adverse Effect?

Agriculture being the backbone of this country has been put to threat in the recent years. In India nearly 700 million rural populations depend upon climate-sensitive sectors such as agriculture, forests and fisheries. Moreover, natural resources such as water, biodiversity, mangroves, coastal zones, grasslands and their livelihoods have also been put into threat. Increased greenhouse gases are likely to impact all the natural ecosystems as well as socio-economic systems. An annual mean surface temperature rises by the end of century, ranging from 3 to 5°C with warming more pronounced in the northern parts of India. A 20% rise in all India summer monsoon rainfall and further rise in rainfall is projected over all states except Punjab, Rajasthan and Tamil Nadu which show a slight decrease. Extremes in maximum and minimum temperatures are also expected to increase and similarly extreme precipitation also shows substantial increases, particularly over the west coast of India and west central India.

GHG concentrations should be stabilized at levels where food production is not threatened (UN, 1992). Without considering the carbon dioxide fertilization effects yield losses for rice and wheat vary between 32 and 40%, and 41 and 52%, respectively. Their study also showed that even with carbon fertilization effects, losses would be in the same direction but somewhat smaller. For a developing country, these are very large changes which can cause much human misery. From India's point of view, a 2°C increase would be clearly intolerable.

Oxygen levels and its isotopic composition in the atmosphere are stable; it takes a major terrestrial change to affect it very much. These changes were huge. The drop-in vegetation growth must have been dramatic. Ocean circulation patterns also can heavily influence climate, and shift in ways that are not completely understood.

Lives of large population in the coastal areas are now put to threat due to the sea level rise and prone to sub-mergence. This will lead to the migration in large scale especially from the low-lying delta regions in the developing countries. Intrusion of sea-water in the ground water and changes in temperature can reduce agricultural and fishing too. If a one-meter sea level rise were to take place today, it would displace 7 million persons in India (ADB, 1995). If this situation prevails in future, the number would be more and there are chances that 35% of the land in Bangladesh would be submerged by a one-meter rise.

Increase in greenhouse gases such as CO₂ and methane (CH₄), and other anthropogenic emissions into the atmosphere, can be expected to have significant impacts on forest ecology, forest distribution, and productivity. The projected impacts of climate change on forests also have implications for forest product flows and trade and forest management.

Large forest areas of Sundarbans have turned into forest villages with heavy with carbon dioxide in the environment. Local people destroy mangrove forest of the region unknowingly; they do not know the concept of climate change and global warming. India is experiencing some of the very real effects of climate change. Sundarbans is losing 100 km² every year (Tables 2 and 3).

Functioning of Ozone Layer and its Depletion

Ozone is a gaseous substance which is created at the upper part of the atmosphere by photochemical reaction between molecular oxygen, oxygen atom in presence of solar radiation in a continuous fashion. Main function of ozone layer is to protect earth from the dangerous ultraviolet radiation (about 97%–99%) of the sun. On absorption of ultraviolet light, ozone dissociates into oxygen which become ozone again as mentioned earlier maintaining a balanced situation. But the alarming situation is that ozone layer is getting thinner day by day thereby passing a portion of the harmful UV radiation.

Table 2 Precipitation change projections for India due to increasing GHGs

Year	Precipitation change (%)			Sea level rise (cm)
	Annual I	Monsoon	Winter	
2020s	1.36 ± 0.19	1.61 ± 0.16	1.13 ± 0.43	4–8
2050s	6.7 ± 8.9	-2.9 ± 26.3	6.7 ± 8.9	15–38

Source: Aggarwal, D., Lal, M., 2001. Vulnerability of Indian Coastline to Sea-level Rise, New Delhi: Centre for Atmospheric Sciences, Indian Institute of Technology.

Distribution of ozone depends on the geographic location and season. Ozone layer is located in between 10 and 50 km above the surface of the earth. Observations from worldwide ozone monitoring units (also known as Dobson unit, named after British meteorologist G.M.B. Dobson) noted that more than 95% of total atmospheric ozone concentration is found at an altitude ranging between 15 and 20 km is supposed to be in danger. More than 50% ozone content of this zone has been destroyed.

Depletion of ozone layer takes place due to both natural and artificial. However, natural phenomenon such as stratospheric wind or sun-spots is responsible for depletion of ozone layer by not more than 1%–2%.

Main cause of ozone depletion is due to human related activities. Day by day the concentration of chlorine and bromine is increasing from industrial production of chlorofluorocarbon or CFC, halogens, methyl chloroform, carbon tetrachloride, hydro fluorocarbons etc. These chemicals are termed as ozone depleting substances. Chlorine is very destructive for ozone. Every chlorine atom can destroy thousands of ozone molecules. Commercially produced CFC is available in various grades. However, the amount of damage to the ozone layer by any agent is expressed in terms of CFC-1. The equivalence is carried out by ozone depleting potential or ODP. Ozone depleting agents generally possesses a relatively longer life span and hence they continue to deplete ozone layer long after their emission. ODS are relatively stable in atmosphere. Stability of these substances pushes them to the upper portion of the stratosphere where ultraviolet light dissociates them to ultimately form chlorine or bromine.

It is already discussed that ozone filters out harmful UV radiation contained in sunlight. When ozone is depleted, UV rays reaches earth. Exposure to UV radiation has serious impacts on all living being.

Impacts of Ozone Depletion on Living Being

Human and animal

- Chances for skin cancer increases.
- Eye diseases.
- Weakening human immunity system.

Agriculture

- Reduction of growth rate for various crops such as rice, wheat, oats, peas etc.

Other impacts on eco-system

- Planktons (micro-organisms, vital in marine food chain) are damaged on exposure to UV radiation. This reduces fish yields, thereby losing biodiversity.
- Besides, construction materials like wood, rubber etc., are degraded on exposure to UV radiation.

Noting the detrimental effects of ozone depletion, various nations have taken a remarkable step by joining hand together. 194 nations signed an international agreement (Montreal protocol) to stop commercial production of CFC and other ODS. However, more concern as well as awareness is required to forbid usage of ODS.

Kyoto Protocol

Different anthropogenic activities such as extraction of energy from fossil fuels, deforestations, industrial development etc., have resulted in increase in Greenhouse Gas (GHG) level beyond normal values since a long. This is the main reason of increase in the average temperature of earth in an uncontrolled fashion. Carbon dioxide, Methane, Nitrous oxide, Chlorofluorocarbon, oxide of sulfur etc., are generally treated as greenhouse gases (GHGs). Major constituent of GHG is carbon dioxide which mainly originates from combustion of fuels. Kyoto protocol is a treaty between different Nations of the World to commit reduction of greenhouse gas consumption to control the detrimental effects caused due to global warming.

Incoming solar radiation can penetrate the layer of greenhouse gases at the upper layer of atmosphere but gets entrapped when reemitted from earth in the form of infrared radiation. In this way GHG is capturing heat day by day, thereby increasing the average temperature of this planet. This rapid increase in temperature has become a matter of great concern in present day. Keeping this grave situation, awareness is required for proper implementation of sensible strategy at the international level. Basically, Kyoto protocol is based on different obligations particularly for the developed countries on the fact that they are responsible for the present level of greenhouse gases due to their continued emission over a long period.

United Nations Framework Convention on Climate Change (UNFCCC)

The awareness started in 1992. In order to promote sustainable development, a common platform was required so that different nations can act together in order to save environment. The common platform was named as United Nations Framework Convention on Climate Change (UNFCCC). This framework imposed non-binding limits on greenhouse gas emissions for individual nations having no provision for any kind of enforcement mechanism. However, in Earth summit, there was an outline for specifying international treaties or protocols. Presently, there are 192 nations attached with the protocol (Canada withdrew in 2002). This protocol encouraged industrialized nations to stabilize GHG emissions. For each level of different component of GHG, different levels of emission reductions were required to stabilize their concentration on atmosphere.

Flexibility in Meeting Targets

Emission targets for industrialized countries participating in Kyoto protocol are expressed as allowed emission levels over commitment period of 2008–2012 was denominated in tones of CO₂ equivalent emissions.

Economical basis for providing flexibility was that the marginal cost of reducing the emission was different at different parts of the globe. Surveys conducted in this regard suggested that flexibility mechanisms could reduce overall cost of achieving the targets.

Although industrialized countries should take necessary action to reduce the detrimental effects of climate change, however Kyoto protocol allows flexibility in meeting their emission reduction targets through market-based mechanisms mentioned below.

Kyoto Mechanisms

Three mechanisms were adopted in Kyoto protocol, namely: Emission Trading, Joint Implementation and Clean Development Mechanism.

Carbon market used by these mechanisms is a key to monitor reduction of emission worldwide.

CDM and JI were two project-based mechanisms feeding carbon market. CDM involves investment in sustainable development-based project works while JI promotes industrialized countries to join hands among each other.

Although more than 160 countries signed Kyoto protocol, the USA, larger emitter of GHG did not ratified Kyoto Protocol.

International Emission Trading

Emission trading is an innovative market based mechanism proposed at Article 17 of the Kyoto Protocol.

A number of emission trading schemes have been implemented. In different countries, different agencies were given responsibility to take care about this. European Union framed Emission Trading Scheme (EU ETS) allowed trading of national Kyoto obligations between participating countries, known as Carbon Trust.

Generally, the pollutant emission is treated as a commodity and the price for emission is decided on the reduction target or 'emission cap'. The term 'cap' denotes total amount of the regulated pollutant in certain units that is accepted globally to be

emitted on yearly basis. The cap value is set at particular emission values and then divided into allowable levels which are distributed between all the participating units. This allowance can be traded in market.

Main objective of this is to set limit on total emission by the larger emitters of GHG. Individual nations have mandatory emission targets to meet.

If the units emitted in a year is less than its allowance level, then that nation can sell its excess allowance. On the other hand, if the emission is more than the allocation level, then the concerned nation has to buy allowances to cover its excess emission. In this way countries with lesser emission can sell emission units to the countries which have crossed their emission targets. In view of the fact that carbon dioxide is the major GHG constituent, other polluting emissions can be converted in terms of their carbon dioxide equivalence, hence this marketing is known as "Carbon-Market". Countries taking part in carbon market has to meet their commitment on targeted emission per year otherwise they have to buy compliance with a variable rate depending on the situation. If the cost in carbon market is high, then the nations will be either forced to utilize energy efficiency or they have to explore different renewable energy resources. Both this possibilities ultimately reduces the overall GHG emission. Localized emission trading has been already implemented in Europe in order to reduce GHG from industry. Such localized process may intend to link up ultimately in a globalized system, under Kyoto protocol.

Joint Implementation (JI)

Joint Implementation is proposed at Article 6 of Kyoto protocol. The basis of JI is financial as well as technical cooperation between Annex I countries for implementation of clean and renewable energy and promoting energy efficient projects among them. This is another way of mitigation of GHG emission. An Annex-I country can invest in a energy efficient project or renewable energy project in another Annex-I country, thereby reducing carbon dioxide emission in the atmosphere. In this process emission reduction units (ERU) is allotted to the former nation thereby mitigating its emission target.

Clean Development Mechanism (CDM)

Clean development program or CDM is proposed in article 12 of Kyoto Protocol. Basis of CDM is that any Annex-I nation can invest in a sustainable development program in a non-Annex-I nation. CDM allows project based flexible trading between developed and developing countries in order to help each other to mitigate the target for GHG emission. Main difference between JI and CDM is that the former is implemented between Annex-I nations whereas the later involves cooperation between an Annex-I and a non-Annex-I nation. Both of these mechanisms involve energy efficient projects generating emission reduction credits CER (Certified Emission Reduction), directly crediting to investor's account.

Basically, CDM helps both an Annex-I country and a non-annex-I country in a cooperative manner. Utilizing this mechanism an Annex-I nation can achieve its target on emission reduction commitment while a non-Annex-I nation can achieve sustainable development by providing a revenue to the developing countries.

To decide the price of trading many attempts were made. Price estimation is based in the result of economic models and various identification factors. In the carbon market, the price estimation was decided on the basis of emission of per ton of carbon dioxide. Initially, it was decided that the price range should be between 3 \$ and 74 \$ (US dollar) per ton of carbon dioxide.

CDM found its effectiveness in promoting renewable energy projects. This will help the developing nations to enrich their economy. Rural development in developing countries will be enriched by implementing distributed generation. Industries will take part in sustainable development by implementing energy efficient projects through optimal resource allocation. Urban lifestyle will be improved by various waste processing projects. This will help in maintaining balance in ecosystem.

CER generated from CDM projects financially or technically or both have become a source of revenue for developing countries. Mainly clean and renewable energy projects, fuel switching, waste treatment projects, energy efficient techniques, energy management etc., are included CDM projects. Renewable energy-based power projects gained attention because they do not emit any GHG at any stage. So, such projects can earn revenue through carbon market on per unit (kWh) electricity production. It is observed that on an average approximately 1.486 kg carbon dioxide is emitted for per unit electricity production from a coal-based thermal power plant. This is obtained from stoichiometric analysis of coal. If more efficient technologies can bring down the capital investment cost on green energy-based projects, then its carbon profit will be more.

Introduction to Energy Management

Energy is the key factor to for the development of human civilization. Tremendous research works giving birth to newer technologies day by day. With the advancement of technological growth, harnessing energy has become a matter of great concern. Different application of technologies requires energy utilization in different forms. Among all other forms, electrical energy is the most compact form. It is a very good intermediate form of energy and very ease to transmit and distribute. Besides, it can be

converted to any other form of energy with ease. However, a major portion of energy is lost during energy conversion. The term 'energy loss' may sound as misleading because according to the law of conservation of energy cannot be created, nor can be destroyed and only can be transferred from one form to the other. The logic of using the term 'energy loss' is that, during conversion of energy from one form to other or in transmitting and distributing, a certain portion of energy is converted to heat which cannot be utilized to perform any useful work. So, from economics point of view it is a loss because the process is consuming energy but cannot utilize it fully due to inherent *heat loss*.

Energy resources can be categorized as renewable and non-renewable. Non-renewable resources are fossil fuel-based resources and renewable resources include solar, wind, hydel etc.

Basically, fossil fuel-based resources possess very high energy-density than renewable resources and energy extraction from fossil fuel is already existing through well-established popular and developed technologies. But, main problem with these types of resources is that these are finite by nature. Besides, extraction of fossil fuel involves emission of polluting agents, mainly greenhouse gases and is responsible for the detrimental effect of global warming.

On the other hand, renewable resources are clean by nature because they do not emit greenhouse gas or any kind of polluting agent. However, main limitation of renewable resources is low energy density in comparison to fossil fuel-based resources. Extraction from renewable resources is also not popular or well established though tremendous research and development works are carried out globally to find efficient and cheaper techniques to harness renewable resources. However, it is a fact that harnessing of fossil fuel is usual practice.

Per capita energy consumption is an economic indicator to judge the standard of living of the people in a nation. High consumption of energy is correlated with a quality life specified by the term gross national product (GNP). The main problem in present time is the increasing per capita energy consumption on daily basis due to technological development. This is very alarming because if this situation continues, fossil fuel will not sustain in distant future. On the other hand, renewable resources alone cannot meet the need for energy demand due to lower energy-density. But economic growth cannot be sacrificed and hence per capita energy consumption has to be maintained at a reasonable level.

One way to tackle this situation is an optimized mix of renewable and fossil fuel-based resources which are achieved through various techniques such as co-generation, tri-generation, energy conservation, energy efficiency and energy management.

Co-generation system produces multiple forms of useful energy in a single (usually mechanical and thermal), integrated system simultaneously. Mechanical energy is generally used to produce electricity through generators or can be utilized to blow fans and compressors. Thermal energy is utilized in heat processing applications such as to produce steam, hot water or hot air for drying.

On a similar note, tri-generation is the production of electricity, heat and cooling in a single, compact system simultaneously. One example for tri-generation is a gas fired power plant generating electricity and heat with the exhaust heat going to an absorption chiller which produces chilled water and hot water for air conditioning or alternatively the heat is used in process industries. The ratio of electricity produced and exhausts heat for the absorption chiller and then the ratio of cooling to heating can be varied to meet the demand.

Energy conservation denotes efficient and judicious energy consumption. This is synonymously related to energy efficiency which permits consuming lesser energy to achieve the same level of work done. To achieve energy efficiency, total system performance should be considered. This is because with the increase in system components, overall system efficiency goes down, no matter how efficient individual components are.

Energy management comprises of two sides – supply side management and demand side management.

Supply-side management (SSM) refers to measures taken to ensure efficient conversion, transmission and distribution of energy. This has become a matter of great importance with the deregulation of the electricity industry in many countries, where the efficient use of available energy sources becomes essential to remain competitive. SSM is mainly correlated with electricity; however, it can also be applied to actions concerning the supply of other forms of energy. Utility companies always look for a flat load profile for economic operation of their plant. But, unfortunately, due to the continuously varying nature of load, compels them to run peak load power plants running on less efficient equipments which are needed to be operated for as small duration as possible (compared with high efficiency equipment that should be used to the maximum). Utility companies may improve maintenance and control of existing equipment, or upgrade equipment with state-of-the-art technologies for more efficient and economic utilization of energy.

Demand-side management (DSM) or demand-side response (DSR), is the modification of consumer demand for energy through various methods such as financial incentives and behavioral change through education. The term DSM was coined following the time of the 1973 energy crisis and 1979 energy crisis. The main objective of demand side management is to encourage the consumer to use less energy during peak hours, thereby moving the time for energy usage to off-peak hours. This reduces peak loads often supplied by peak load boilers running on more expensive and less sustainable fuel. Peak demand management does not necessarily decrease total energy consumption, but could be expected to reduce the need for investments in networks and/or power plants for meeting peak demands. Latest trend for DSM is to aid grid operators in balancing intermittent generation from wind and solar units, particularly when the timing and magnitude of energy demand does not coincide with the renewable generation. Governments of several countries have mandated performance of various programs for demand management.

Presently, DSM technologies have gained popularity due to the integration of information and communications technology and the power system, thereby resulting in a new term: smart grid. In energy sector, DSM focuses to at reduce the demand for electricity and energy sources. DSM helps to reduce greenhouse gas emissions.

It is evident from the above discussion that major concern should be given to demand-side management methods (DSM). However, some aspects of supply side managements should be considered too. For example, they may look at on-site generation alternatives – including cogeneration – or consider diversifying to alternative fuel sources (such as natural gas, solar, wind, bio-fuels etc).

Environmental Impact Assessment (EIA)

Environmental impact assessment (EIA) is an interdisciplinary procedure to consider environmental implications before making final decision regarding a proposed project.

Purpose of EIA is to inform decision makers and public about the environmental consequences of any proposed project. Basically, EIA is a technical tool that identifies, predicts or analyses several activities proposed in the project and their effect on the environment. The EIA process serves an important procedural role in overall decision making by transparency and involvement of mass.

An effective EIA should predict the possible change in environment due to proposed human activities.

During the planning of a project, EIA can be treated as an essential step to mitigate sensitive socio-economic issues, if any. Benefits of EIA process can be stated as under:

Screening of projects which are not eco-friendly.

- Reduced cost and time of project implementation.
- Avoidance of environmental impacts, if any and obeying existing rules and regulations.
- Prediction of hazardous impacts.
- Improved performance of the concerned project.
- Identification of potentially affected communities or individuals.
- Proposition for any modification on a proposed project to override environmental impacts.
- Achieving socio-economic development but without sacrificing biodiversity.
- Decreased extraction of resources, thereby help to achieve sustainable development.
- Conflict between nature and mankind is minimized.
- Increased community skills and cultural enhancement.

Depending on the EIA system, either by government agency/ministry or proponent for the project is assigned with the responsibility for producing EIA.

Duration of EIA will depend upon the size and complexity of the proposed project, the extent of co-operation of the parties involved in the proposed project, EA techniques employed etc.

It is important to recognize a general principle of assessment relating to the review of environmental impacts that might be obtained from a proposed project.

The following are well recognized processes:

- Social impact assessment
- Risk assessment
- Energy analysis
- Life cycle analysis
- Health impact assessment
- Economic assessment
- Regulatory impact assessment
- Cumulative impact assessment
- Strategic impact assessment

EIA involves several important purposes, which can be enumerated below

- Decision making
- Process to aid development
- Achieving sustainable development

The process of EIA is closely related with sustainable as well as community development **Fig. 5**.

EIA is carried out through a systematic process to check environmental attributes due to the development action in advance. Hence, it is proactive by nature. EIA process involves a number of steps. Few of them are listed below:

- Screening of project
- Scoping and consideration of alternatives
- Baseline data collection
- Impact prediction
- Assessment of alternatives, delineation of mitigation measures and environmental impact statement
- Public hearing
- Environmental management plan (EMP)
- Decision making and preparation of environmental impact statement (EIS)
- Post-decision monitoring and clearance conditions

Fig. 5 Illustration of sustainable development. Source: <https://www.semanticscholar.org/paper/EIA-follow-up-Roles-and-stakes-in-environmental-Morrison-Saunders-Arts/0d0ccaa02085a3b6f31ed436f905d23e4502b6b7>.

Steps involved in environmental cleaning can be explained by the following diagram in Fig. 6.

However, procedure involved in EIA can be analyzed with the help of Fig. 7 as given below.

EIA studies are broadly classified as under:

- Site election studies
- Comprehensive studies
- Regional studies
- Carrying capacity studies

EIA cycle can be explained with the following diagram (Fig. 8)

EIS provides valuable information regarding the proposed project. A typical EIS is prepared with the following three parts:

- Part 1 – methods and key issues
- Part 2 – background of the proposed project
- Part 3 – environmental impact assessments on topic areas

Adoption of EIA has evolved since last few decades. USA was the first country in the globe to mandate EIA through NEPA act, 1969. Developed countries adopted EIA in between 1970–1980.

India initiated implementation of EIA in 1976–77 by active cooperation between Planning commission and Department of Science and technology. After thorough monitoring of several projects with environmental angle, Government of India enacted The Environment (Protection) Act, on 23rd May 1986. In 2000, EIA was made statutory for 30 activities.

The ministry of Environment and Forests (MOEF) has prescribed guidelines for different sectors to be addressed during EIA studies. Generally, impacts of air, noise, water, land nature, biodiversity, and socio-economic condition of local people are assessed.

Carbon Sequestration

Carbon Sequestration is a natural or artificial process by which carbon dioxide is removed from the atmosphere and held in solid or liquid form.

Carbon Sequestration is an effective tool for mitigating emission targets as prescribed in the Kyoto protocol. Kyoto protocol allocates CER to promote carbon sequestration activities. This encourages forestation or reforestation or agriculture thereby reducing CO₂ concentration in the atmosphere.

It has been observed that global (both atmospheric as well as marine) accumulation of CO₂ can be absorbed by carbon sequestration.

Fig. 6 Step-by-step procedure involved in environmental clearance. *Source:* The manual in perspective, EIA Training Resource Manual, United Nations Environment Program, 2002.

With respect to the growing concerns about global warming resulting from increased concentration of greenhouse gases (GHG) in the atmosphere, considerable interest has been drawn to the possibility of increasing the rate of carbon sequestration. CO₂ is merely responsible for the detrimental effect of global warming which is the increase of average temperature increase of earth by entrapping heat from solar radiation in the form of infrared radiation.

CO₂ can be naturally captured from the atmosphere through natural biological, chemical and physical processes. Various artificial processes also have been incorporated to yield similar results. This includes artificial capture and sequestration of CO₂ originated from various industries using subsurface saline aquifers, reservoirs, ocean water or other carbon sinks.

Carbon sequestration mainly carried out in three ways: post-combustion capture, pre-combustion captures and oxy-combustion.

Carbon sequestration can be effectively implemented through changes in the utilization of land as well as forestry and also through geo-engineering techniques such as carbon capture and storage.

Carbon is released in atmosphere both from human related anthropogenic activities such as the burning of fossil fuels as well as from various natural processes such as the combustion and decomposition of vegetation or animal. On the other hand, carbon sinks are those reservoirs that retain carbon and prevent it from entering in the atmosphere. Water and plant are two main and natural sinks for CO₂. Hence, afforestation or reforestation can effectively reduce concentration of atmospheric CO₂. Plants fix carbon through photosynthesis. It is the process through which a major portion of carbon is transferred naturally from the atmosphere to the biomass reservoir in the presence of solar radiation at chlorophyll. Beyond the natural growth of plants, other terrestrial processes such as of replacement vegetation on cleared land, land-management practices etc., can sequester carbon. It is important to note that carbon sequestered in soils and aboveground vegetation could be released again to the atmosphere through land-use or climatic changes such as combustion (which is caused by fires) or decomposition (which results from microbe infestation).

Fig. 7 Procedural steps involved in EIA. *Source:* Prof. Sandeep Hegde's resource material.

Carbon is transported in various forms through the atmosphere, the hydrosphere, and geologic formations. An important link for exchange of carbon is the atmosphere and the oceans. A fraction of the CO_2 combines with water, forming carbonic acid (H_2CO_3).

Carbonate entrapped in soil may become buried in geologic strata and eventually release CO_2 through volcanic eruption. Carbon dioxide is also exchanged through photosynthesis in plants and through respiration in animals. Dead and decaying organic matter may ferment and release CO_2 or methane (CH_4) or may be incorporated into sedimentary rock, where it is converted to fossil fuels. Basically, the biological and anthropogenic activities occur at a faster rate than the geochemical processes and hence possess a greater impact on the composition and temperature of the atmosphere.

Globally, the total amount of carbon sequestered in nature is approximately 2200 gigatons (1 gigatons = 1 billion tons), and it is estimated that the amount of carbon sequestered annually by terrestrial ecosystems is approximately 2.6 gigatons.

Oceans also accumulate carbon, and the amount found just under the surface is roughly 920 gigatons. Various studies showed that amount of carbon stored in the oceanic sink exceed the amount in the atmosphere (about 760 gigatons).

Carbon Capture and Storage

There are many economic as well as technical challenges to implementing carbon capture and storage on a large scale. It has been estimated that carbon capture and storage would increase the cost of electricity production up to five cents per unit, depending on the fuel geographic location of the site. Leakage of carbon from reservoirs is also a matter of great concern. Though various reports show that properly managed geological storage is very reliable (66%–90% retentively) to store 99% of its sequestered carbon dioxide for over 1000 years.

Basically, three types of carbon sequestration techniques are available to implement carbon sequestration. These are terrestrial, geological and mineralization which are discussed below:

Terrestrial Sequestration

Terrestrial sequestration is the removal of existing CO_2 and storage of the same with the help of vegetation and soils through afforestation, reforestation, wetland recovery etc.

Fig. 8 Representation of EIA in cyclic form. *Source:* Prof. Sandeep Hegde's resource material.

Geologic Sequestration

This involves storage of CO₂ in subsurface structure in oil reservoir, natural gas reservoirs, deep saline formations, shale reach in oil or gas, and in coal beds unsuitable for mining etc.

Mineral Sequestration

It is the process of forming stable carbonate salts by chemical reaction of various substances mainly magnesium and calcium with CO₂. It is a natural process which is responsible for producing limestone.

Geological sequestration among others possesses greater viability due to its substantial storage capacity. Besides, most of the major anthropogenic sources of CO₂ emission are located near potent geological storage sites.

Technologies for Carbon Sequestration

Carbon sequestering technologies include a geo-engineering proposal called carbon capture and storage (CCS). CCS is carried out through two interrelated steps.

Firstly, carbon dioxide is separated from other constituents emitted in various industries. After separation, the CO₂ is compressed and transported through pipelines to a location that is isolated from the atmosphere for long-term storage. Suitable storage locations might include geologic formations such as deep sedimentary rocks whose pore spaces are saturated with water containing high concentrations of dissolved or in depleted oil and gas reservoirs, or in the deep ocean. Although CCS captures carbon dioxide directly at the source of emission before releasing into the atmosphere, it may also include techniques to remove carbon dioxide from the surrounding air. Separation of CO₂ can be done through the following three methods.

- *Pre-combustion capture*

This treatment is carried out before burning of the fuel. The fuel is converted to synthesis gas or syngas and then ultimately to hydrogen and CO₂. After that, hydrogen is separated from CO₂ and is used as fuel.

- *Post-combustion*

After burning of fuel, CO₂ is separated from nitrogen using chemical agents.

- *Oxy-fuel combustion*

Fuel is burnt in pure oxygen so that nitrogen is not present in the emission.

In the second step, CO₂ in supercritical form (liquid stage) is injected into underground geological formations.

Obstruction for Carbon Sequestration

The challenges encountered by carbon sequestration are mainly technical, financial or regulatory by nature.

CO₂ is mainly stored underground by hydraulic pressure so that it is stored in supercritical (liquid) state. In case of minor fault in tank design or any form of even very small leakage will ease the pressure on the liquid CO₂, thereby releasing it into the atmosphere in gaseous form.

CCS techniques would increase the operational cost for energy production. If CCS is mandated through regulatory action, then cost of production of electricity would be nearly double in a coal-based thermal power plant. The cost of CCS technology varies with different types of capture technologies being used. The cost also depends on concerned sites that it is implementing CCS. It is obvious that research and development may reduce the cost for CCS technologies still it would remain slightly higher than costs involved in technologies without CCS.

Energy required for sequestration technique is also a significant factor. As an example, it can be stated that any power plant implementing CCS has to supply a significant amount of energy for pumping of CO₂, thereby reducing its effective output.

Responsibilities of Energy Managers

- (1) Preparation of annual activity plan and present to management concerning financially attractive investments to reduce energy costs.
- (2) Establish an energy conservation cell within the firm with management's consent about the mandate and task of the cell.
- (3) Initiate activities to energy costs.
- (4) Analyzing equipment performance with respect to energy efficiency.
- (5) Checking the functioning and calibration of instrumentation required to conduct energy audit.
- (6) Convey awareness about the importance of energy audit with real time data among the staff members associated with the plant concerned.
- (7) Establish a methodology to calculate the specific energy consumption of various products/services or activity of the plant concerned.
- (8) Develop and manage training program for energy efficiency at operating levels.
- (9) Co-ordinate nomination of management personnel to external programs.
- (10) Develop integrated system of energy efficiency and environmental up gradation.
- (11) Co-ordinate among various implementation techniques of energy audit/efficiency improvement projects through external agencies.
- (12) Establish and/or participate in information exchange with other energy managers of the same sector through association.

Energy Intensive Equipments

Following are energy intensive equipments consuming a large portion of energy for their proper operation

- Industrial drives
- Heating/cooling equipment such as oven or chiller/ cooling tower
- Lighting
- Intra-transport for goods as well as staff members or labors
- Pumping system
- Combustion chamber
- Ventilation and air conditioning equipment
- Purifying equipment such as electrostatic precipitator (ESP) or air filter
- Heat or water treatment plants etc.

Energy Conservation Opportunities

Substitution of fuel (if possible), efficient energy conversion methodologies, economic feasibility etc., are easily identifiable provisions energy conservation.

Proper fuel air ratio or any efficient fuel can decrease the energy consumption level. Similarly, it can be stated that efficient energy conversion methodologies should be adopted in order to achieve economy in energy consumption. Captive power generation, optimal loading of distributed generation, waste heat recovery, flue gas heat recovery, pre-heating etc., are various ways to improve system efficiency wherever applicable. Economic feasibility is the key parameter for adopting energy management policies. This is carried out through various economic tools such as payback period, internal rate of return, net present worth etc. It is mention-worthy that economic feasibility is also depended on technical viability which involves availability of proper techniques, skilled manpower, reliability, safety, quality etc.

Classification of Energy Conservation Opportunities

Based on the report from detailed energy audit, several potent energy saving projects may be figured out. These may be classified as per the following:

- (1) Low cost-high return projects
- (2) Medium cost-medium return projects
- (3) High cost-high return projects

Obviously, projects possessing low cost and high return are prioritized. Other options are analyzed further and implemented in a phase by phase manner. Projects involving high cost with high return are given careful attention before implementing. Commencement time of such projects may be very high.

Energy Efficiency and Conversion Efficiency of Energy

Energy efficiency either refers to efficient usage of energy or efficient conversion of energy.

Efficient usage of energy or simply energy efficiency is consumption of less energy to provide same level of performance than in a normal situation. As an example, it can be stated that installation of LED lights instead of incandescent or fluorescent light will decrease the energy usage level but providing same amount of illumination. Energy efficiency is an essential criterion to achieve energy conservation (Russell, 2006). Energy efficiency is a cost-effective strategy in order to achieve overall economy as well as sustainable development.

Energy conversion efficiency is the ratio between the useful output and the input for an energy conversion device. Due to inherent losses, output energy is always lesser than the input energy. The objective of energy conversion efficiency is to minimize the inherent losses, if possible. Energy conversion efficiency cannot be defined uniquely, because it is case specific.

Conclusion

The effects of global warming are the environmental and social changes caused (directly or indirectly) by human emissions of greenhouse gases. There is a consensus that climate change is occurring, and that anthropogenic activities are mainly responsible for this. Several impacts of climate change have already been observed, including glacier retreat, thermal expansion of large water-bodies and changes in agricultural productivity.

Future effects of climate change will vary depending on climate change policies and social development. The two main policies to address climate change are reducing human greenhouse gas emissions (climate change mitigation) and adapting to the impacts of climate change.

Very short-term climate change policies could significantly affect long-term climate change impacts. Besides, environmental pollution does not follow the boundary of a country and hence it is not a localized phenomenon.

Stringent mitigation policies might be able to limit global warming (in 2100) to around 2°C or below, relative to pre-industrial levels. Without mitigation, increased energy demand and extensive use of fossil fuels might lead to global warming of around 4°C. Higher magnitudes of global warming would be more difficult to adapt to and would increase the risk of detrimental impacts like severe thunderstorms and flash flooding etc.

The effects of global warming include its effects on human health. The observed and projected increased frequency and severity of climate related impacts are mentioned below:

- *Impact on infectious diseases*
- *Impact on respiratory system*
- *Impact on vascular disease*
- *Impact of extreme weather*
- *Malaria*
- *Dengue fever*
- *Psychological impact*

The global health care sector is highly interconnected with industrial activities emitting a significant portion of environmental pollutants. Environmental emissions directly and indirectly attributes to the physical as well as mental health care sector. Negative environmental and public health outcomes were estimated through economic input-output life cycle assessment (EIO-LCA) modeling using National Health Expenditures (NHE) for the decade 2003–2013 and compared to national totals in USA.

Concerted efforts from all corners of people to improve environmental performance of health care could reduce expenditures directly through waste reduction and energy savings, and indirectly through reducing pollution burden on public health, and ought to be included in efforts to improve health care quality and safety and reduction of hospital bills.

Thus, based upon the current impacts of the climate change, it is very clear that the controversies to be created in the future would be really aggravated than thought. Hence, it is now in our hands to take up the responsibility of shaping the planet as it was before. Maybe it is now late in taking decisions but there is very little time to implement it. We have exploited our mother nature

to the maximum as we could and now, we are being repaid. Adhering to the latest technologies available in the market, we have the capability to advance easily into the industrial practices. Indian industry is quite adept at absorbing technology. Most of the technologies are already available. In fact, if you are talking about steps on climate change, almost 90% of the technologies are available. Unless you are talking about clean coal technologies or carbon sequestration, it's not an issue.

Introduction

The ever increase demand of energy and power has caused serious irrecoverable damage to our environment. With this continuous demand of energy and the regular increasing usage of fossil fuels to meet the needs of the various industries an increase in the amount of greenhouse gases in the nature has been observed. These greenhouse gases pose serious hazards to our environment and causes consequent climate change. The prominent gases causing greenhouse effect include Carbon Dioxide, Methane, Nitrous Oxide, Ozone and Chlorofluorocarbons (11 and 12). Out of these gases it has been estimated that Carbon Dioxide is the major greenhouse gas. The individual contribution of all these gases to greenhouse effect is shown in [Table 1 \(Rodhe, 1990\)](#).

With these being a serious issue an important and concerning issue is their increasing concentration in our environment. Their increase in concentration every year has been estimated and shown in [Table 2 \(Rodhe, 1990\)](#).

The increase in the greenhouse gases every year has some serious effects on the environment. They have caused global warming to increase at an unappreciable and concerning way due to which the ice capped mountains and peaks have started to melt and an increase in the water level has been noticed. Acid rains is one of the causes of the increase in the concentration of the greenhouse gases ([Jakobsson et al., 2009](#)). Depletion of ozone layer is a very critical issue. 70%–75% of the Carbon Dioxide is produced by consumption of fossil fuels ([Hoel and Kverndokk, 1996](#)). Apart from the effect of greenhouse gases produced by fossil fuels, the increased demand of fossil fuels increases its cost due to its regular demand. Fossil Fuel depletion has been stated as a future challenge. However these non-renewable sources of energy are bound to deplete in a certain period of time and the only alternate solution to such an increasing demand are renewable sources of energy. So in order to limit the use of the fossil fuels and save the planet from increased global warming which will lead to drastic climate changes the use of renewable energy like wind energy, geothermal, solar and hydro energy are very much into use ([Johansson and Burnham, 1993](#)).

However countries like Japan, China is trying to revolutionize by bringing a new renewable source of energy, Hydrogen cells. Hydrogen links the renewable sources of energy to zero emission technologies. These cells would be used to power fuel cells in order to run the vehicles as well as provide electricity at home ([Behling et al., 2015](#)). The primary steps to use Hydrogen as a primary source of renewable energy was taken in the early 1980s by the European Union.

Hydrogen Fuel: Advantages, Production, Delivery, Storage and Conversion

The thought of hydrogen cells as a source of energy came into being because of climate change and the depletion of the fossil fuels. With the aim of decarbonizing the environment, Hydrogen cells could play an important role. The Hydrogen cells provide the following advantages over fossil fuels:

- Hydrogen production from wind, hydropower, solar, biomass and thermal energy are low polluting emission systems.
- Since no extraction and refining is done as in the case of crude oils, winter smog and acidification will be reduced.
- Air pollution will be decreased as no production of Sulphur Oxides, Nitrogen Oxides and other polluting gases will be formed which shall decrease respiratory problems.
- Eco-friendly means of production of Hydrogen ([Koroneos et al., 2005](#)).

With the following advantages of Hydrogen fuels, Hydrogen production is done by following means:

- Pyrolysis and Gasification.
- Water Electrolysis.

The electrolysis of water is done by utilizing electricity produced using some renewable source of energy. The production of hydrogen in this process is from water which is very readily available in nature. Hence this process is cost effective process as it only involves the costing of the electricity required for the splitting of the water molecule. The major drawback of this technique is the use of platinum electrodes which makes it costly.

- High temperature Nuclear Reactor.
- Production from solar, wind and thermal energy sources.

Wind energy is used to produce electricity by affecting the nature to a minimum. Solar energy is the most used renewable source of energy. These energies are used to produce electricity by keeping the environment in a quasi-static state. This electricity is

Table 1 Individual contribution of greenhouse gases

used to produce hydrogen required in electrolysis of water. Geothermal energy is cheap and is readily available and hence is a good alternative to produce hydrogen. Geothermal energy can be available in electricity or heat form. So hydrogen can be synthesised using electrolysis or hybrid cycles.

- Production from Biomass.

There are two ways to produce hydrogen from biomass: biological and thermochemical. It is produced in the way shown in **Fig. 1** (Hosseini and Wahid, 2016).

- Production from natural gas and coal.

Coal and Natural Gas are used for synthesising hydrogen. Hydrogen is synthesised from Natural Gas by reacting it with water at 20 times the atmospheric pressure and 1000°C. The drawback of this system that for 1 ton of Hydrogen produced almost 2.5 tons of Carbon dioxide is produced which makes it an insignificant process.

Coal produces almost twice the air pollution in comparison to the Natural Gas and it has been shown simultaneously that using coal to produce Hydrogen is uneconomical (Gray and Tomlinson, 2002; DOE, n.d.).

The pyrolysis and gasification hydrogen production when made to mix path with Carbon Capture and Storage aids in removing the Carbon Dioxide from the atmosphere. This is a very important factor in absorption of such technologies. A very important statistics laid by IEA Greenhouse Gases Programme this uptake of this technology could remove 800 million tonnes of Carbon Dioxide on an annual basis in Europe only by replacing fossil fuels (Sgobbi *et al.*, 2016).

Even though this system has so many advantages the main problem lies in the fact that what needs to be established first: the system that would utilize such fuel or the vast infrastructures to produce this eco-friendly fuel.

The increased demand of Hydrogen will lead to its economic manufacturing using the above mentioned processes. However the Hydrogen economy has not gained much attention. Hence for its delivery pipelines only in few places around the world has been established which include Indiana, California, Texas and Louisiana in United States of America and the Ruhr Valley in Germany. It is generally distributed over road transport in cryogenic cylinders which contains Hydrogen in liquid form. Since the volumetric energy density of Hydrogen is very low, hence it needs to be compressed or liquefied for its transportation. However these are not economical processes and research and development team is dedicating their work to optimize the cost in this operations.

Though Hydrogen has the highest gravimetric energy content of any fuel reported till date and is the lightest element, its lower volumetric energy density makes it challenging for its storage purpose. This is one of the most challenging field in comparison to the hydrocarbon fuels which can easily be delivered, stored and carried along. Apart from it needs to be stored in automobile refuelling places which was so easily achieved by hydrocarbon fuels.

Hydrogen so produced can be converted into electrical energy through electrochemical processes by using fuel cells. They can also be converted to thermal energy through thermochemical processes by using turbines and combustion engines. Fuel cells are the future of our world as we aim to provide efficient, clean and fuel-flexible energy to our locality. Fuel cells have proved to be efficient with some cells providing an overall efficiency exceeding 80%. The use of Hydrogen in the engines of Space Shuttle is an old known concept.

Fig. 1 Hydrogen production from biomass. Reproduced from Hosseini, S.E., Wahid, M.A., 2016. Hydrogen production from renewable and sustainable energy resources: Promising green energy carrier for clean development. *Renewable and Sustainable Energy Reviews* 57, 850–866.

Hydrogen Economy and Utilization of Hydrogen Fuel

Hydrogen Economy has different divisions which deals with production, storage, transportation and distribution of Hydrogen fuel. The Hydrogen fuel has found its way in different sectors which include transportation, residential and commercial sectors and industries (Brandon and Kurban, 2017).

Hydrogen in Automobile/Transportation Sector

A new idea and attitude has been seen by engine manufacturers and oil refineries to the increasing carbon content in the nature. Some major steps taken by them include:

- Hybrid electric vehicles.
- Lightweight materials being used for the transportation purposes.
- Direct-injection compression ignition engines.
- Fuel Cell powered electric vehicles.

In order to render the emissions from the vehicles carbonless initiatives has been taken by leading automobile companies like Toyota, BMW, Hyundai, etc. by producing Fuel Cell Electric Vehicles (FCEV). However they still offer only 30% Carbon Dioxide saving as the Hydrogen fuel cells are made from natural gas and coal derivatives (Sgobbi *et al.*, 2016; Ball and Wietschel, 2009) and are costly in the present scenario. Though the prices are supposedly to come down in the coming future with the increased research and development dedicated to this field but in this present scenario the internal combustion engine vehicles and the plug in electrical vehicles are much cheaper compared to them.

It has been experimentally shown by some researchers in 2003 from MIT that the hybrid engines can reduce greenhouse gases to about 65% by 2020, this shift can be understood as well in 2018, in comparison to the non-hybrid conventional engines (Weiss *et al.*, 2003). Hybrid engines were tested for fuel cells and internal combustion engines with the properties under observation was the efficiency and the emission of the greenhouse gases. Along with the advances in power systems to reduce the greenhouse gas emission and increase the efficiency of the vehicles, the important factors which played an important role were the weight of the vehicle, aerodynamic drag and tire rolling resistances. A comparison has been shown by them between Fuel Cells and

Internal Combustion Engines. The Internal Combustion Engines had greater advantages compared to Fuel Cells. The Internal Combustion Engines are much easier to manufacture compared to Fuel Cells because of the existing infrastructure. However the Fuel Cells operate at a very low noise compared to Internal Combustion Engines.

Hydrogen in Residential and Commercial Sectors

The energy consumed by this sector consists of lighting, heating, cooling and for running appliances and equipment. More than 40% of the global energy is used in the residential sector (Brandon and Kurban, 2017). Also it is necessary to decarbonize heat as it is the third in global energy related Carbon emissions. Decarbonizing heat can be done through Though decarbonizing heat energy has not been the major attention seeking subject in this field in comparison to decarbonizing power, this subject needs to be brought into consideration if we are to meet the climate mitigation targets. Decarbonizing heat is challenging in these fields however if the gas network can be converted to hydrogen it would be cheaper to provide low carbon heating.

Hydrogen in Industries

Almost 25% of the global energy is used by the industries all over the world, hence the emissions produced by them leads to carbonizing the environment to a large extent. Hence it becomes necessary to use renewable sources of energy like fuel cells. Fuel Cell is basically a technology which takes Hydrogen as an input source of energy and produces dc power. But it has been observed that most of the Hydrogen is utilized to prepare fertilizers and then industries and methanol synthesis. In the European Union, industries produce Hydrogen as by-products and only 10% is supplied by merchants. Hydrocracking and Hydro-treating techniques are used by oil refineries to refine crude oil. Hydrogen accounts for near about 20% of the total emissions produced by these refineries (European Technology Platform for Zero Emission Fossil Fuel Power Plants, 2013). The demand of Hydrogen has increased with the increased use of heavy oils with clean high quality fuels with less Sulphur content (International Energy Agency, 2015).

Fuel Cells

With increased demand for energy and decreasing Carbon content in the nature, Fuel Cells seems to be a very good alternative as it uses Hydrogen to produce power. There are three types on the basis of temperature: Low temperature, medium temperature and high temperature (El-Sharkh *et al.*, 2004a,b). The low temperature is further classified into the following: Alkaline Fuel Cells, Solid Polymer fuel Cells and Proton Exchange Member (PEM) Fuel Cells. The Medium temperature has Phosphoric Acid Fuel Cells. The high Temperature can be classified into Molten-Carbonate Fuel Cell and Solid Oxide Fuel Cell.

The Hydrogen Fuel Cell consists of reformer (fuel processing unit), power conditioning unit and the fuel cell stack. The low temperature and medium temperature Fuel Cells have external reformers while the high temperature Fuel Cells have an internal based reformer as hydrocarbons can be processed internally at the high temperature provided by them. The output of this is a dc power, which can be supplied to residential complexes, industries with proper conditioning techniques and use of transformers. The material selection of the fuel cell technologies is subjected to various constraints which are subjected to its performance under various conditions. Minimization of cell resistivity is one such important factor as it ensures high energy densities. Hence the combined resistivity of the anode, cathode and the electrolyte, the cell components, should be a maximum of $0.5 \text{ } \Omega\text{cm}^2$. In order to reduce the combined resistivity of the cell the electrolyte, the electro-catalyst, current collector and the gaseous reactants needs to be brought together in a close contact. In order to further reduce the resistivity the electrode a metallic wire, mesh or screen was introduced in the cell. Further reduction was achieved by incorporating high ionic conductivity electrolytes like molten carbonates, liquid KOH or phosphoric acid. The other important component is the impermeable electronic conducting bipolar plate. This serves two function: One is to provide air and fuel to both the anodic and cathodic plates and second is to provide electric contact between adjacent cells. Due to corrosive effects in some membrane fuel cells (polymetric-electrolyte and phosphoric acid) the material to be chosen is severely restricted to certain elements like graphite. Stainless steel derivatives are used for high temperature fuel cells operating in a temperature range close to 750°C . But for solid oxide fuel cell the different bipolar plate materials are different as the temperature of these fuel cells are around 100 (Steele and Heinzel, 2011). However fabrication of graphite plates are expensive, hence polymeric materials are preferred as they can be machined easily and is more cheaply fabricated using injection moulding or hot pressing. Even graphite can be mixed with different materials to make these bipolar materials. With the increase in graphite the mechanical properties like toughness decreases and brittleness increases and machinability decreases, however the electrical conductivity increases. The best electro-catalyst used for operations with Hydrogen and air is platinum. However platinum is a costly element and hence incorporation of nanoparticles of platinum over Carbon. The platinum content has been reduced over the years without affecting the performance of the electro-catalyst. The material should also have reliability and durability properties. The durability should be at least 1000 h for transportation system while for stationary applications this should extend to over 5 years. However, the materials used for these membran fuel cells are having issues which are further overcome by the upcoming new generation of research and development. These systems would not have gathered interest if not for the discovery of the Naflon (Steele and Heinzel, 2011). Naflon was first introduced as membrane cells for the production of Chlorine. But in order to be used in fuel cells the polymeric membranes should have the following properties in the balanced way:

- Permeability of gases must be low irrespective of the membrane thickness.
- Thermal, mechanical and chemical strengths should be good.
- Moisture content in stack should be controlled.
- The proton conduction should be high.

Polymer electrolyte membrane fuel cell has gained importance over other fuel cells because of its application in a quick start-up. This Fuel Cell gained much importance as an exchange resin was incorporated as an electrolyte for the space application. With this incorporation the Polymer electrolyte membrane proved to be better alternatives compared to solar cells and batteries. The working of the fuel cell depended on the cell membrane thickness and the water content in the membrane. The water content increases the conductivity of the membrane, hence more water should improve the performance of the fuel cell, but cathode may get flooded which will slow down the reaction. This is termed as water drag. In order to reduce the water drag, the thickness of the membrane can be reduced and this lowers the resistance of the membrane, decreases the overall cost and increases hydration (Smitha *et al.*, 2005). The membrane materials can be as follows:

- Perfluorinated membranes.
- Partially fluorinated membranes.
- Acid base blends.
- Non-fluorinated membranes with aromatic backbone.
- Non-fluorinated membranes.

Among all the membranes Naflon produced by DU point had gained popularity as it has high proton conducting property, mechanical strength and chemical stability. However efforts are still being made to improve the properties of Nefflon, like water retention at higher temperatures. Silicon has been used to improve the retention property above 130°C (Watkins *et al.*, 1993). Significant changes in the conductivity were observed when perfluorinated ionomers were incorporated in the Naflon matrix along with doping with heteropolyacids. Many such attempts were made to improve the properties so that the overall performance of the fuel cell increases. However there are a still a lot of limitations with regard to Naflon. They are as follows:

- Safety issues during its manufacture.
- Temperature limitations.
- Supporting Element requirements.
- High Cost of the membranes.

With the shortcomings of this membrane, it is expected that it will be replaced in the coming future (Antonucci *et al.*, 1999; Watkins *et al.*, 1993) with the research to overcome these shortcomings going on.

Challenges in Fuel Cells

The challenges faced by the fuel cells are its high expenses and its durability problems. The cost of the fuel cells is generally due to the electrocatalyst, since it contains precious metals, which increases the cost of the actual fuel cell to be almost seven times the target market value. As said earlier the use of nanoparticles are helping this cause and even the introduction of unique nanostructured thin film have increased the properties as well as reduced the cost. This provides 15–20 times more durability compared to the Membranic Electrode Assembly. The other factors which affect the cost of the cells are bipolar plates and the membranes.

For the durability problems, the target running time should be 5000 h but it has been experimentally observed that after 1000 h of running under heavy loading the performance of the system decreases significantly. The fuel cells performance also decreases due to degradation of the catalyst layers and membranes, which in turn is accelerated by the cell potential variation and humidity of the system. Due to their combined effect chemical and physical stresses are induced in the membranes which eventually results in the formation of the pin holes finally leading to membrane failures. It has also been observed that the fuel cells cannot operate at all vehicle temperatures i.e., -40°C to $+40^{\circ}\text{C}$. This makes it less competitive compared to Internal Combustion Engines (Chalk and Miller, 2006).

Conclusion

With the increase in the greenhouse gases there are various irrecoverable impacts on the nature, like global warming, climates changes, melting of snow caps, etc. Hydrogen being one of the best alternatives has shown much promise in various studies. Its production from renewable sources being the best possible scenario to decarbonize the environment. A number of ways has been suggested by the researchers to produce Hydrogen gases, with production from biomass being the most efficient while the production from natural gas being the most cost effective. The hydrogen economy though seems to be a very promising and reliable idea but the concept to come into existence will take much more years as predicted by the researchers. The use of Hydrogen in the automobile sector is one of the best ways to decarbonize the environment. However the question of durability and efficiency comes into play as Internal Combustion Engines' durability is high and then comes the cost terms, which is very high for Hydrogen based vehicles. The biggest problem faced by this sector is that the transportation, storage and distribution of Hydrogen at cheaper rates. The Fuel Cells are a very important future technology which has a tendency to cause the 'Hydrogen Revolution'.

With the recent progress going on over fuel cells to decrease the cost of the fuel cells and increase its mechanical and electrical properties, this revolution may be far but not impossible because in many parts of the world the Government has taken actions to develop Hydrogen Economy. Hence, Hydrogen Power and the Fuel Cells are the essential tools of clean energy with the help of which mitigation of greenhouse gases can be done and a better and greener future can be ensured.

CO₂ Sequestration Using Algal Biomass and its Application as Bio Energy

Ranjana Das, Swati Das, and Chiranjib Bhattacharjee, Jadavpur University, Kolkata, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

According to the Intergovernmental Panel on Climate Change (IPCC), emissions of global greenhouse gases (GHG) have enhanced the average global temperature at the end of the 21st century by 1.1–6.4°C (Intergovernmental Panel on Climate Change IPCC, 2007), with a proposal of reducing global greenhouse gas (GHG) emissions by 50%–80% by 2050 (Intergovernmental Panel on Climate Change IPCC, 2001). Emissions of anthropogenic CO₂ are generally a consequence of fossil fuels being the most important global energy sources. The demand of energy has been increased significantly in recent years because of the rapid development of modern industries. At present scenario, the most challenging mission for many countries, to find alternative energy resources specifically for those countries lacking fuel resources (Huang *et al.*, 2010). So, for reducing CO₂ emissions, exploration of renewable energy should be emphasised. Therefore, carbon sequestrations are required for balance energy efficiency and renewable energy to reduce global CO₂ emissions. Carbon sequestration is the one of the most effective process of storing atmospheric CO₂ which is removed from the atmosphere. It has also emerging as promising ways of 'geo-engineering' and mitigating the crisis arising global warming. Carbon sequestration involve two important segments namely (i) carbon capture (the capturing of large quantities of CO₂ for carbon sequestration) and (ii) carbon storage (successfully storage of the captured CO₂, finding a safe, protected, and cheap place). This article aims to present an outline of CO₂ sequestration techniques through natural resources as a trail to alternative fuel. This article has explored the potential of algae for CO₂ sequestration and as a source of sustainable alternative fuel source.

CO₂ Sequestration and Associated Facts

Recent studies present that atmospheric carbon dioxide has increased from about 280 ppm in 1750–383 ppm in 2007 and is increasing at an average rate of 2 ppm (parts per million) per year. Carbon sequestration has been recognised as potential way to reduce greenhouse gas emissions. It also complements two other major approaches for greenhouse gas reduction, namely improving energy efficiency and increasing use of non-carbon energy sources. It's emerging as important field of research because of its compatibility with the large energy production and delivery infrastructure. All the potential routes for removal of CO₂ from air or industrialized flue gas stream has been classified as, physicochemical routes, geological routes and biological routes. In physicochemical process, capturing of CO₂ from industrial flue gas streams involves application of several unit operations like absorption, adsorption, gas separation by membranes and cryogenic distillation. Geologic sequestration has been assumed as most perpetual method for carbon sequestration and part of a process frequently referred to as 'carbon capture and storage' or CCS. Geologic sequestration refers to a promising technology to reduce CO₂ emissions to the atmosphere and mitigate climate change. Geologic sequestration process involves the steps of injecting carbon dioxide, captured from an industrial (like, steel and cement production) or energy-related source (like, a power plant or natural gas processing facility), into deep subsurface rock formations for long-term storage. Underground injection of CO₂ also serves the purposes of enhanced oil recovery (EOR) and enhanced gas recovery (EGR) as a long-standing practice. CO₂ injection specifically for GS involves different technical issues and potentially much larger volumes of CO₂ and larger scale framework. This is Geologic sequestration has been considered as reliable and reassuring if the geologic formations embattled for carbon sequestration and can prevent the discharge of carbon dioxide in the environments.

Bio sequestration is the capture and storage of the atmospheric carbon dioxide by biological processes by various routes like, increased photosynthesis (through practices of reforestation or preventing deforestation and genetic engineering; enhanced soil carbon trapping in agriculture; and algal bio sequestration. Biological routes include algal systems and energy crops like corn, oil palm, switch grass which can utilize CO₂ from the atmosphere using photosynthetic pathway. The carbohydrates and polysaccharides can be transformed to hydrocarbon fuels through various thermochemical processes such as pyrolysis, refraction, liquefaction and gasification and several biochemical methods like anaerobic digestion and fermentation (Nanda *et al.*, 2014). Coal bed methanogenesis has also been categorised as biosequestration which involve use of methanogenic bacteria that degrade the coal bed and produce biogenic methane to capture carbon from atmosphere.

Bio sequestration is the process of capturing and storage of CO₂ in living organisms such as plants and algae. It has been given utmost priority being simple, and being responsible for the formation of the extensive coal and oil deposits which have potential fuel application. The term 'biosequestration' was coined for one of the solutions to help balance greenhouse gas and carbon emissions as part of climate change policy. The photosynthetic organisms such as several bacteria, algae which can be inhabited marine as well as freshwater environments are abandoned and the microbial route has been reported more advantageous over other chemical process because of their very spontaneous assimilation methodology. The progressive routes for carbon capture and sequestration can be shown in Fig. 1.

Fig. 1 The routes for carbon capture and sequestration.

Cement plants generate concentrated amounts of carbon dioxide producing 1.25 metric tons of CO₂ for every ton of cement produced. On average each plant produces 100,000 tons of CO₂ per year. According to the Intergovernmental Panel on Climate Change, there are more than 1175 cement production facilities globally that in 2000 collectively generated 932 million tons of CO₂. Because cement plants generate copious amounts of CO₂, and many are located in tropical or subtropical regions of the world, they are ideal candidates to take advantage of algae technology to convert stack gasses to algae oil.

Carbon Sequestration Using Algae as Green Energy Feedstock

Developed and developing nations to meet the demand of energy crisis utilise conventional sources of energy which inevitably increases the CO₂ emissions which ultimately results in increased environmental fouling and pollution. At present the energy, Industry and transportation sectors release the CO₂ in a bulk volume. Under Kyoto Protocol agreement, the targeted value of CO₂ was established to meet the sustainability for a better tomorrow which helps us to mitigate the level of pollution. Thus the concept of green development has come to researcher's mind. As CO₂ is the main contributor to global warming, it must be captured. Recently, lot of different kinds of pathways are available, among them the biological route of CO₂ capture using microalgae is under our immense research attention due to its simplicity in production, less by-product at different stages which reduces the cost of the process as well as the consumption of energy (Nanda *et al.*, 2014). This section has covered the potency of microalgae as fuel alternative, the salient features of algal fuel, details of the CO₂ fixation methodology, different aspects of algae production and optimisation aspects of algal biofuel.

Algae are photosynthetic diversifying organisms which can be found anywhere in the world, and their presence is in aquatic environment in bulk quantity. Algae may be unicellular or may be multi-cellular in nature and the word 'algae' can be denoted as a polyphyletic and collection of synthetic microorganisms (Apt and Behrens, 1999). In presence of sunlight, CO₂ and nutrients; their photosynthetic pigments produce food. Algae are the largest producer of oxygen in the environment. Near about 50% oxygen is produced by the algae (Chisti, 2000, 2007; Gavrilescu and Chisti, 2005; Wijffels, 2007). Being primary producer algae provides the baseline in the aquatic food chain. Due to its wide availability in the environment, it is used as bio indicator which reflects the different kinds of alteration in the environment in different phases of time. Pollution level indexing is done by different kinds of algae. Algae are generally classified in two kinds, namely, microalgae and macro algae. Microalgae are basically microscopic in nature (Scott *et al.*, 2010), while, in case of macro algae, generally they are visible in naked eyes (Smith, 1944). The length of microalgae is basically from few micrometres to few hundred micrometres. But in terms of macro algae they are generally larger than microalgae having thallus like structure. According to various critical factors like pigmentation, thallus structure, reserve food material, flagellation and reproduction; algae are classified in different classes among which *Chlophyceae sp.*, *Cyanophyceae sp.*, *Rhodophyceae sp.*, *Bacillariophyceae sp.* and *Euglenophyceae sp.* are the most commonly found algae in aquatic environment (Benemann *et al.*, 1978). Algae are significant source of

important biomolecules, like (i) lipids, (ii) carbohydrates and (iii) proteins. Lipids and carbohydrates can be used as fuel precursors like biofuels, biodiesel and gasoline and proteins can be used as animal's nutrient (Ferrell and Valerie, 2010). Comparisons of oil yield between different feedstock for production of biofuel has been presented in Table 1. It was studied that microalgae are superior alternative as a feedstock for large scale biofuel production (Metting, 1996; Spolaore *et al.*, 2006). That's why microalgae biomass is preferred for the large scale -biofuel production.

CO₂ Sequestration and Fixation Using Algae

Cultivation of Micro Algal Biomass and Salient Features

Photosynthesis is the most promising process to store CO₂ in form carbohydrates using the solar energy and water. Microalgae have done their photosynthesis process in chloroplast of their cell. Photosynthesis process of sequestering CO₂ by algae may be harnessed either in (i) light dependent photosynthesis process (in this stage the light energy is harnessed and conserved in the form of ATP and NADPH by the chlorophyll and sun light harvesting compound) (ii) light independent photosynthesis process (ATP and NADPH are consumed in the time of carbohydrates synthesis). Algae production typically achieved by (i) Photo autotrophic where inorganic carbon and light are required, (ii) Heterotrophic where organic carbon and light are required in this mechanism and (iii) Mixotrophic mechanism where autotrophic photosynthesis and heterotrophic assimilation are required for production of microalgae.

Usually algae have been cultivated, in either open raceway ponds or closed photo-bioreactors system (Jiménez *et al.*, 2003a). Brennan and Owende (2010) have demonstrated raceway pond a closed loop and oval shaped recirculation channels as presented in Fig. 2. Horizontal tubular photo-bioreactor including arranged straight glass or plastic tubes can be shown in Fig. 3. Ugwu *et al.* (2008) The tubular array structure was made for better capturing of sunlight and to avoid microbial contamination and to assure pure algal cell growth within the system (Huntley and Redalje, 2007; Rodolfi *et al.*, 2009). In 2012, (Ketheesan and Nirmalakhandan, 2012) have considered an airlift-driven raceway reactor for microalgae culture to obtain highest CO₂ consumption. According to Cheng *et al.* (2006), it was observed that retention time of CO₂ has enhanced in photo bioreactor to enhance efficiency of CO₂ fixation. CO₂ fixation using microalgae through closed photo-bioreactors have been reported by several researchers (Fulke *et al.*, 2010; de Moraes and Costa, 2007; Chiu *et al.*, 2008; Giripunje *et al.*, 2013). Various microalgae species like *Chlorella vulgaris*, *Scenedesmus obliquus*, *Chlamydomonas reinhardtii*, *Spirulina sp.* and *Botryococcus braunii* were used for CO₂ fixation and sequestration (de Moraes and Costa, 2007; Chiu *et al.*, 2008; Giripunje *et al.*, 2013; Packer, 2009; Fulke *et al.*, 2013). Numerous numbers of research publications have established the importance of carbon capture using algal biomass and production of biofuels from microalgae as favourable and eco-friendly methodology for carbon dioxide sequestrations (Fulke *et al.*, 2010; Packer, 2009; Shekh *et al.*, 2013; Ramanan *et al.*, 2010, 2012).

Table 1 Comparisons of oil yield between different sources for production of biofuel

Feedstock	Oil yield (L/acre)
Soybean	181.68
Corn	68.13
Rapeseed	480.69
Sunflower	386.07
Canola	495.83
Oil palm	2403.47
Jatropha	788.33
Microalgae	19,000–57,000

Biofuel Production Using CO₂ Sequestered Algae

CO₂ Fixation Through Algal Biomass Production

The CO₂ is fixed in the growth period of algae through various processes such as formation of biomass, mineralization where atmospheric CO₂ can be converted to chemical compounds such as carbonates and bicarbonates and construction of extracellular products like polysaccharides, unstable organic compounds, various hormones and halogen containing organic compound (Sydney *et al.*, 2014). All of them, biomass formation is the key aspect, where 70% – 88% of total CO₂ fixation was created in the period of algal cultivation (Sydney *et al.*, 2014). Hence, the researchers have explored the potential of biomass for CO₂ fixation. The CO₂ fixation ability of microalgae have been summarized in Table 2.

Advantage and Disadvantages of Algal Biomass for Biofuels Production

Micro algal biotechnology has developed due to the pronounced multiplicity of products of algal biomass. Sustainability is the key factor in production of bioenergy, particularly the biofuels, as a part of future generation of fuel development from algal biomass. Some advantages and disadvantages of biodiesel production using algal biomass have been summarized in Table 3.

Table 3 Advantages and disadvantages of biofuel production using algal biomass

Aspects	Advantages	Disadvantages
Cost	It is made from renewable resources	Currently more expensive than other fossil fuel
Air pollution	Significant reduction of particulate matter (PM) emissions	Caused increases in nitrogen oxide (NO _x)
Greenhouse gas (GHG) emission	Significantly less harmful carbon (CO ₂ , CO) emission using algae	Reduction of fuel economy
Energy security	Viability of the first generation biofuel production	Conflicts with food supply
	Relatively less flammable compared to fossil diesel	Less suitable for use in low temperatures
Usage	Significantly improved lubricating properties	More likely than fossil fuel to attract moisture
	Significantly less harmful carbon emission compared to other fossil fuel	
Energy availability	Fossil fuel is a limited resource, but biofuels can be manufactured from a wide range of materials	Sometimes more fossil fuel energy was required to produce algal bioenergy. Few Life Cycle Analyses (LCA) from algal biomass have shown (–ve) energy balance

Factors Affecting Microalgae Growth for Biofuels Production

Several environmental factors which are affected the algal growth for production of biofuel. Energy such as light, carbon abundance, nutrient availability, environmental parameters like temperature, pH, salinity and inhibiting compounds have an impact on algal metabolism and shown in the [Table 4](#).

Harvesting of Algal Biomass for Production of Biofuel

For large scale biofuel of productions from microalgae, selection of efficient harvesting method is recognised as crucial point ([Amaro et al., 2011](#); [Uduman et al., 2010](#)). Selection of the suitable harvesting technique has great importance to the economics of biofuels production. The appropriate technique of harvesting depends on the several micro-algal characteristics like the density and size of algal cells as well as the product derived from the algal biomass ([Amaro et al., 2011](#)). Typical microalgae harvesting methodology involve two-steps. (i) Bulk harvesting, aims to separate micro-algal biomass from the bulk suspension which can be done by several physical methods like, flocculation, flotation, or gravity sedimentation with total solid algal biomass concentration of 2%–7% w/v ([Brennan and Owende, 2010](#)). (ii) Thickening, targets to concentrate the slurry with filtration and centrifugation process, requiring high energy of processing than bulk harvesting ([Brennan and Owende, 2010](#)). Several literatures have briefed the possibility of suitable harvesting strategies based on several unit operations like, centrifugation, sedimentation, flocculation, flotation and micro-filtration ([Amaro et al., 2011](#)). A comparative analysis between different methods of harvesting has been summarized in [Table 5](#).

Algal Biomass Conversion Into Biofuel

The major biofuel products from algal biomass are bioethanol, biodiesel, bio-hydrogen, and biogas ([Singh and Olsen, 2011](#)). In the conversion of biofuel, alcohols are derived from sugars fermentation or conversion of cellulosic biomass through a combination of hydrolysis and fermentation or gasification and synthesis, traditional biodiesel (mono-alkyl esters made from trans-esterification of vegetable or animal triglycerides), and synthesis fuels of alcohols and alkanes (gasoline, diesel) produced from gasification of biomass. Biofuels produced from algae and the respective yield values has been summarized in [Table 6](#).

Algal oil extraction from the biomass involves two steps, namely mechanical extraction and chemical extraction. Mechanical methods include, expression or expeller press and ultrasonic-assisted extraction. Crushing in conjunction with the chemicals also practiced for better extraction for some specific varieties with medium lipid content. The use of ultrasonic reactor (sonochemistry), greatly speed up the extraction processes.

In chemical extraction route, algal lipid extraction is assisted with use of solvents, like benzene, hexane and ether have been well recognised solvent system for extraction of lipid. The technique of hybrid pressing and solvent extraction process has been reported to increase the yield value of the lipid more than 95% of the total oil present in the algae. Supercritical CO₂ extraction method has been developed for extraction of lipid but being highly expensive not practiced industrially.

Table 4 Environmental factors affecting microalgae growth for biofuels production

Factor	Organism	Conditions	Result	References
Carbon Source	<i>Dunaliella salina</i>	CO ₂ concentration increased from 2% to 10% for 7 day	2.7 fold increase in fatty acid	Muradyan <i>et al.</i> (2004)
	<i>Chlorella zofingiensis</i>	under glucose concentration of 5–20 g L ⁻¹ in Heterotrophic culture	Maximum specific growth rate 0.031 h ⁻¹ at glucose concentrations of 20 g L ⁻¹	Ip and Chen (2005)
	<i>Spirulina platensis</i>	Elevated CO ₂ concentrations	Decrease in proteins content and also pigments and increase in carbohydrate content;	Gordillo <i>et al.</i> (1998)
Temperature	<i>Botryococcus braunii</i>	Increased from 25 to 32°C	Decrease in intracellular lipid content from 22% to 5% (dry weight) with significant accumulation of polysaccharides	Kalacheva <i>et al.</i> (2002)
	<i>Chlorella vulgaris</i>	Increased from 20 to 38°C	Decrease in starch component resulting in increase in sucrose	Nakamura and Miyachi (1982)
		Increased from 10 to 38°C	Transformation of L starch (high molecular weight) to S starch (low molecular weight) reversible with temperature	Nakamura and Imamura (1983)
	<i>Haematococcus pluvialis</i>	Increased from 20 to 30°C	3-times increase in fatty acid formation	Tjahjono <i>et al.</i> (1994)
	<i>Nitella mucronata Miquel</i>	Increased from 5 to 20°C	Increase in velocity of cytoplasmic streaming	Raven and Geider (1988)
	<i>Dunaliella viridis</i>	Darkness (No light)	Increase in total lipid content Decrease in free fatty acids, alcohol, sterol	Gordillo <i>et al.</i> (1988)
	<i>Chlorococcum sp</i>	Temperature increase from 20 to 35°C under nitrogen deprivation	Two fold increase in total carotenoid content	Liu and Lee (2000)
Light	<i>Porphyridium cruentum</i>	Red light	Enhanced Photosystem II relative to Photosystem I and phycobilisome	Cunningham <i>et al.</i> (1990)
	<i>Nannochloropsis sp.</i>	Light limited conditions	Increase in lipid content	Sukenik <i>et al.</i> (1989)
	<i>Chlorella vulgaris</i>	Red light	Increase in sucrose and starch formation	Miyachi and Kamiya (1978)
		Blue light	Increase in lipid fraction and alcohol–water insoluble non carbohydrate fraction	
pH	<i>Chlamydomonas acidophila</i>	pH 4.4	Denaturation of V-lysin	Visviki and Palladino (2001)
	<i>Coccochloris penicystis</i>	pH decreased from 7.0 to 5.0 and 6.0	Decrease in total accumulated carbon and oxygen evolution	Coleman and Colman (1981)
Effect of reaction time	<i>Spirogyra</i>	higher the reaction time 10 to 25 min	The higher yield (above 95%) was obtained at 25 min of reaction time.	Shah <i>et al.</i> (2015)
Nitrogen source	<i>Nannochloropsis oculata</i>	75% decrease in Nitrogen	Increase in lipid synthesis from 7.90% to 15.31%	Converti <i>et al.</i> (2009)
	<i>Chlorella vulgaris</i>	75% decrease in Nitrogen	Increase in lipid synthesis from 5.90% to 16.41%	Converti <i>et al.</i> (2009)
	<i>Phaeodactylum tricornutum</i>	Nitrogen limitation	Increase in lipid synthesis; Decrease in protein content	Morris <i>et al.</i> (1974)
	<i>Haematococcus pluvialis</i>	Nitrogen limitation	Increase in carotenoid formation (13% w/w)	Borowitzka <i>et al.</i> (1991)
phosphorus concentration	<i>Chlamydomonas reinhardtii</i>	Limitation of phosphorous	Decrease in phosphatidylglycerol	Sato <i>et al.</i> (2000)
	<i>Ankistrodesmus falcatus</i>	Limitation of phosphorous	Enhance in carbohydrate and lipids	Healey (1982), Healey and Hendzel (1979)
	<i>Selenastrum minutum</i>	Starvation	Reduced rate of respiration; Decreased photosynthetic CO ₂ fixation	Theodorou <i>et al.</i> (1991)
Iron concentration	<i>Dunaliella tertiolecta</i>	Limitation	Decrease in cellular chlorophyll concentration	Greene <i>et al.</i> (1992)
	<i>Chlorella vulgaris</i>	High concentration of iron	Increase in lipid content	Liu <i>et al.</i> (2008)
	<i>Haematococcus pluvialis</i>	High concentration of iron was required	Increase in carotenoid formation	Kobayashi <i>et al.</i> (1993)

(Continued)

Table 4 Continued

Factor	Organism	Conditions	Result	References
Salinity	<i>Dunaliella tertiolecta</i>	increased in NaCl concentration from 0.4 to 4 M	Increased in saturated and mono unsaturated fatty acids	Xu and Beardall (1997)
		increased in NaCl concentration from 0.5 to 1.0 M was observed	Increase in intracellular lipids (60% to 67%) and triglyceride concentration (40% to 56%)	Takagi and Yoshida (2006)
	<i>Tetraselmis suecica</i>	High salinity	reduction in protein content per cell of up to 20% with increasing salinity	Fabregas <i>et al.</i> (1984)

Table 5 Comparative analysis between different methods of harvesting

Harvesting method	Advantages	Disadvantages
Filtration	(1) High recovery efficiency of biomass (2) Can be scaled up (3) Easy for bulk harvesting	(1) Fouling of membranes (2) Energy intensive process
Coagulation flocculation	(1) High efficiency (2) Simple and easy to establish (3) Sustainable and low in energy input	(1) Chemical flocculants cause accumulation of harmful compounds in biomass. (2) Not suitable for high value added products
Screening	(1) Methods of screening are very simple (2) Easy to operate	(1) Clogging of screens due to micro-algal slime (2) High operational cost
Gravity sedimentation	(1) Cost effective process (2) Easy to operate (3) Bulk harvesting	(1) Slow rate of separation (2) Not suitable for very small microalgae
Centrifugations	(1) Highly efficient process (2) Up to 98% recovery of biomass (3) Can be scaled up	(1) Energy intensive process (2) High maintenance costs
Floatation	(1) Simple and effective process (2) Can be made efficient in combination with other harvesting methods	(1) Low harvesting efficiency (2) Some methods may damage the cells
Ultra-sonication	(1) Simultaneous recovery of product possible (2) Easy to operate (3) Can be scaled up	(1) Energy intensive process (2) May lead to damage of cells
Electrophoresis	(1) High efficiency (2) Combines different methods (3) Scale up not possible	(1) Energy intensive process (2) Non-sustainable

Large Scale Micro Algal Cultivation for Production of Biofuels

Open Pond System for Algal Culture

In 1890, Beijerinck *et al.* (Borowitzk, 1999) has studied the physiology of the plants using the first unialgal cultivation with the microalgae *Chlorella vulgaris*. In Germany algal cultivation has been increased using open ponds for food supplement in the time of Second World War. Most industrially applied cultivation systems are open pond system because of its low cost of investment and working capital. Fig. 4 is the schematic presentation of the open pond system. Although these systems have severe problems associated with control of working environments hence, causes lower biomass productivity and highly susceptible to microbial contaminants from other (Suh and Lee, 2003). Closed photo bioreactors have been reported to produce improved biomass yield value with high efficiency of photosynthesis compared to the open pond system. The most commonly used open pond systems include either raceway ponds or circular ponds (Suh and Lee, 2003; Chiaramonti *et al.*, 2013; Kumar *et al.*, 2015). The sump-assisted raceway ponds have been designed for improved CO₂ - liquid contact period. In this system, CO₂ gas was injected in the counter-current direction to increase the liquid/gas contact time. Since the gas was introduced at the bottom of the sump having greater depth, it preferentially allows an enhanced contact time of gas phase and liquid phase. Better CO₂ utilization efficiency and minimization of the CO₂ loss into the atmosphere has been achieved by this system (Kumar *et al.*, 2015; Mendoza *et al.*, 2013; Craggs *et al.*, 2012). de Godos *et al.* (2014) have reported the biomass productivity through the sump-assisted raceway pond as 17 g m⁻² d⁻¹ with approximately 66 % capturing CO₂ from the inlet gas stream. For further enhancing the period of CO₂ liquid contact, atmospheric air was used to flow and produce velocity of the liquid (de Godos *et al.*, 2014). Lam *et al.* (2018) have published a review highlighting different strategies to control the biological contamination during microalgae cultivation in open pond. Baldev *et al.* (2018) have presented a research article highlighting the prospect of the open raceway pond system for culture of *Chlorella vulgaris* as resource material for biodiesel production.

Fig. 4 Schematic representation of the biofuel production from algal biomass.

Closed Pond System and Photobioreactor for Algal Culture

Closed pond system algal culture has been studied in large scale to produce algal biofuel. In closed ponds system the control over the environment being easier than open ponds reduces the chance of contamination but at the expense of reduced light penetration, which affects the cultivation process. Though its initial construction cost is much higher than the open pond system but comparatively lower than photobioreactor. The idea behind the closed pond is to close it off, to cover a pond or pool with a greenhouse. While dimensionally it results smaller system, but evades many of the problems associated with open system. Closed system allows more species to be grown, allows the species that are being grown to stay dominant, and it extends the growing season, only slightly if unheated, and if heated it can produce year round. These systems having the provision of increasing the amount of CO₂ facilitating the algae growth rate.

Photobioreactor (PBR) is closed equipment which provides a controlled environment and enables high productivity of algae. As it is a closed system, all growth requirements of algae are introduced into the system and controlled according to the requirements. PBRs facilitate better control of culture environment such as carbon dioxide supply, water supply, optimal temperature, efficient exposure to light, culture density, pH levels, gas supply rate, mixing regime. Photobioreactors also offer some other advantages like potential for much higher productivity, large surface-to-volume ratio, maximum efficiency in using light and therefore greatly improve productivity (typically the culture density of algae produced is 10–20 times greater than close pond), better control of gas transfer, reduction in evaporation of growth medium, uniform temperature control, space saving (may be placed vertically, horizontally or at an angle, indoors or outdoors), tube self-cleaning mechanisms can dramatically reduce fouling. An enclosed PBR design will enhance commercial algal biomass production by keeping algae genetics pure and reducing the possibility of parasite infestation. Some major limitations in commercialization of the PBR high capital cost, the productivity and production cost in some enclosed photobioreactor systems are not much better than those achievable in open-pond cultures, difficulty in sterilizing these photobioreactors. Design of an ideal high performance PBR involves (i) minimization of the volume of the non-illuminated parts of the reactor, (ii) the design must provide for the uniform illumination of the culture surface and the fast mass transfer of CO₂ and O₂, (iii) mechanical cleaning or sterilization for prevention of fouling of light-transmitting surfaces, (iv) energy consumption required for mass transfer and the arrangement of the light-receiving surface of the algal suspension must be reduced to its minimum possible. Moreover, the commercial microalgae cultivation system depended on growth pattern of algal species for biofuels production are given in Table 7.

Advanced Technologies to Improve Algal Biofuels Production

Utilization of microalgae in bioenergy production have the probability to meet the requirement of a technically and economically viable biofuel resource, because it is economically viable than petroleum fuels, requires no additional land use, enables air quality improvement (e.g., CO₂ sequestration). Microalgae were evaluated as a potential fuel source till 1970s, but the lack of technical knowledge and the production cost have dejected the commercial microalgae-based biodiesel production. The important technical barriers, such as slow growth rate, low biomass production and low lipid contents, need to be overcome before microalgae can be used as an economically viable biofuel feedstock. Hence to make the algal fuel system technologically sound and feasible researchers are concentration on the advanced technologies with an aim to get more biomass and the fuel material from the algal system. To improve the yield value of the of the fuel material (lipid content) of the algae, there different technical modifications have been attempted so far; the first one is the application of genetic engineering approach to improve the lipid yield in algal biomass. The second approach is controlling of the metabolic pathways in microalgae for more biomass and lipid production, and to control the environmental parameters to improve the protein and lipid content of the algae. This section aims to present the effect technological advancement on algal culture and biofuel production.

Genetic Modification of Algae

Application of genetic engineering concept to improve the yield of algal biomass has been studied by several researchers. This section highlights the role of genetic engineering as an ultimate solution of the associated technical problems and also the future prospective of microalgae based biodiesel. Application of genetic engineering approach has been recognised as the best strategy to develop biofuel

Table 7 Growth pattern of different algal strains at mass cultivation prospect

Cultivation system	Name of the algal species	% of Lipid content	Biomass formation	Reference
Raceway pond	<i>Nannochloropsis gaditana</i>	22	19.9 (g m ⁻² d ⁻¹)	Nurra <i>et al.</i> (2014)
	<i>Botryococcus braunii</i>	48.4	1.9(g L ⁻¹)	Ashokkumar <i>et al.</i> (2014)
	<i>Spirulina platensis</i>	–	13.5 (g ⁻² d ⁻¹)	Jiménez <i>et al.</i> (2003b)
Photobioreactors	<i>Chlorella zofingiensis</i>	54.5	58.4 mg L ⁻¹ d ⁻¹	Rodolfi <i>et al.</i> (2009)
	<i>Nannochloropsis sp.</i>	60	0.30 (g L ⁻¹ d – 1)	Feng <i>et al.</i> (2011)
	<i>Chlorella sp</i>	–	4.3 g L ⁻¹ d ⁻¹	Doucha and Lívanský (2009)

production from microalgae in a cost effective way. Due to the absence of cell differentiation, the genetic manipulations of microalgae have become a much simpler system compared with higher plants. Substantial developments in micro algal genomics have been achieved through in depth researches like, an expressed sequence tag (EST) database has been developed, nuclear, mitochondrial, and chloroplast genomes from several microalgae have been sequenced. The knowledge of microalgae genome sequences has greatly simplified the genetic manipulation, and easy access to microalga research. Research publications have summarized several nuclear genome sequencing ventures on a broad range of microalgae (Radakovits *et al.*, 2010). Details on genetic transformation of the microalgae for biofuel production have been reported elsewhere (Radakovits *et al.*, 2010).

Genetic Engineering and Lipid Metabolism

The precursor of biodiesel from algae is the lipid content. The variation in lipid content from various species has driven the research on improvement of the lipid content by controlling the lipid metabolic pathway. The quantity and quality of diesel precursors from algal strain are closely linked to lipid metabolism. This field of research is still at the stage of infancy and lipid biosynthesis, catabolism, the pathway to modify the length and saturation of fatty acids, have not been as thoroughly investigated for algae. The transgenic overexpression strategies have resulted in the increased production of triacylglycerol in seeds and in other plant tissues like soy bean (*Glycine max*), and rapeseed (*Brassica napus*). Since the overexpression strategies to increase storage lipid content was not effective for algal species, an alternative approach have been suggested and reported by a group of researchers based on blocking of metabolic pathway approach. Another approach of increasing the cellular lipid may be achieved by blocking the metabolic pathways which ultimately lead to the accumulation of energy-rich storage compounds, like starch. Starch-deficient strain *C. reinhardtii*, have disruptions in the ADP-glucose pyrophosphorylase and accumulate increased levels of TAG during nitrogen deprivation. Overexpression of the lipid biosynthesis genes (encoding acetyl-CoA carboxylase) and a plant thioesterase, have reportedly to result 20-fold increase in free fatty acid production of *E. coli*, by decreasing lipid catabolism. Inactivation of gene responsible for activation of both TAG and free fatty acids, and those genes involved in β -oxidation of fatty acids, has also reported to increase cellular lipid content.

Another strategy of increasing the biofuel production from algal cell can achieve by modification of lipid characteristics specifically to increase the quality of the lipid with regard to suitability as a diesel fuel feedstock. The carbon chain length and degree of unsaturation of the fatty acids from microalgal species significantly affect the cold flow and oxidative stability properties of biodiesel fuel. Usually, fatty acids from most microalgae offer chain length between 14 and 20, higher percentage being, 16:1, 16:0, and 18:1 fatty acids. Typically, C_{12:0} and C_{14:0} fatty acids are recognised as ideal fatty acids for diesel production. Fatty acid's chain lengths are controlled by acyl-ACP thioesterases activity. There are several acyl-ACP thioesterases from a variety of organisms that are specific for certain fatty acid chain lengths, and transgenic overexpression of thioesterases can be used to change fatty acid chain length. Results have shown that expression of a 12:0-biased thioesterase from *Umbellularia californica* in both *A. thaliana* and *E. coli* drastically have changed the lipid profiles with a great increase in the production of lauric acid (C_{12:0}). Publications have also presented that 14:0-biased thioesterase from *Cinnamomum camphorum* after expressed in *A. thaliana* and *E. coli*, have resulted significantly increased production of myristic acid C_{14:0}. Hence, application of 'thioesterases' for transgenic overexpression in microalgae could improve the suitability of microalga-derived diesel feedstock. Some fatty acids with shorter chain lengths have been recognised as gasoline and jet fuel. Researches have claimed that genetically engineering microalgae directly produce shorter chain lengths of fatty acids. Transgenic overexpression of an 8:0- and 10:0-biased thioesterase from *C. hookeriana* in canola seed has been reported to increase production of short chain fatty acids. Hence the knowledge of gene characteristics, metabolic pathways can effectively be employed for getting more lipids and the fuel precursor from call biomass. Sometimes environmental stress also helps in lipid synthesis hence by creating stress condition in the environmental factors lipid storage in algal biomass have been enhanced. Shortage of nitrogen lowers the proliferation rate consequently energy storage products are produced.

Reutilization of Algal Biomass

In biofuel production process after removing of oil and starch from the microalgal biomass remaining biomass can be used as methane and feed for cattle, used as biofertilizer because of its higher N: P ratio (Wang *et al.*, 2008). Algal biomass has potential application in removing heavy metals, uranium, toxic chemicals and other impurities from wastewater and they can also degrade poisonous poly aromatic hydrocarbons which is usually mixed with petrochemical effluent. Nowadays, the extreme concern in agricultural field is the use of chemical fertilizers which harm the soil and vegetation and algal biomass can resolve the issue serving as green manure. Algal biomass helps in nitrogen fixation, and various microalgae species like Nostoc, Anabaena, Oscillatoria, Cylandrosperrun fix nitrogen by aerobic digestion process and used as biofertilizers (Singh *et al.*, 2016). Algal biomass can be used as bio pigments. Three main pigments namely, chlorophyll (blue light), red carotenoids (blue light and green light) and can be absorbed by phycobilins (green, yellow, and orange light) have been used as natural pigment in food industry. *Phycocerythrin* and *phycocyanin* has pigments which can be provided natural colours in food, pharmaceutical drug, and cosmetics to avoid the carcinogenic synthetic colour (Richmond, 1990). Algal biomass has been used as precursor of antibiotics like acrylic acid found in *Phaeocystis poucht*, which are capable in preventing the growth of gram-positive micro-organisms. The extracts of the diatom species such as *Asterionella notata* has an antifungal and antiviral activity. Toxic algae have been utilized as a depressant vessel (Richmond, 1990). Algal biomasses have also been attempted as biopolymers to produce decomposable plastics depending

on the ecological environments (Jau *et al.*, 2005). The algal biomass having immense value to utilise and need proper exploration for unique green applications like, zooplankton enrichment, bio-energy technology, bio-fertilizer, molecular farming, bioremediation of water and soil and over all environmental protection with green approach. Globally algae are responsible for 50% of the production of photosynthetic biomass and they are abundant feed sources of biofuels.

Conclusion and Future Prospect

Algal biofuels have excellent impact on environmental protection, social and economic sustainability. The bio refinery of algae was aimed for production of an extensive range of biofuels from algal biomasses with reduced environmental pollution at low expense. Biofuel production from algae should assimilate other ecologically sustainable technologies like carbon sequestration, toxic oil degradation from petrochemical industry and the purification of toxic water from agricultural wastes and produced valuable products. Several biofuels can be generated from liquid fuels such as bioethanol, biodiesel, green diesel and jet fuel and biogas, syngas and bio-hydrogen and other gas fuels which can be used in industries and as feedstock for refineries. To frame algae-to-energy systems in reality, substantial research need to be continued in different aspects like, genetic improvements, bio refinery and microbial fuel cell concept development, and integration of alternative energies to CO₂ treatment systems. This algal technology offers a safe and sustainable solution to the problems associated with global warming.

Though algal biofuel is a promising bioenergy source but production of biofuel from algal is too lavish to be commercialized due to the static cost during oil extraction process and biofuel processing and the variability of algal-biomass production. Moreover, utilization of the microalgae for producing value-added products and integration with chemical technologies have now been designed to reducing the cost of algal-biofuel production as future technological development.

Introduction

Co-firing is the process of burning two different types of fuel simultaneously to generate heat or electricity. Co-firing is generally done to get environmental benefit by using renewable energy without significant cost involvement. Coal is the mostly used fossil fuel in the world and combustion of coal emits greenhouse gases (GHG) which are considered to be detrimental to the Earth's atmosphere. Among these different gases, CO₂ is considered to be contributing the most because of two factors: (i) CO₂ represents the largest emissions of all global anthropogenic GHG emissions and (ii) CO₂ has a very high residence time in the atmosphere. Whereas, biomass is renewable energy source and it does not add net CO₂ to the atmosphere because plants as source of biomass consumes the same amount of CO₂ from the atmosphere during growth as is released during combustion. Therefore, use of biomass with coal for energy production will reduce CO₂ emissions by substituting coal feed with a renewable fuel. Recently, the interest in co-firing has grown due to increasing concern about global warming and GHG emissions leading to new policies on energy and the environment to reduce emissions. Co-firing is regarded as the most attractive option for replacing coal used for power generation with renewable fuels at lower costs to result in direct decrease of greenhouse gas emissions. There are many advantages of co-firing of biomass in coal based power plants and some of the important advantages are discussed below (Verma *et al.*, 2017).

- Co-firing of biomass is the easiest way to increase the use of biomass for power generation
- Co-firing of biomass to the existing coal fired power plants can be done with little modification which implies little investment cost
- Opportunity of using different biomass materials with coal which can diversify the fuel portfolio in existing coal fire power plants
- In case of coal shortage, import substitution with biomass will significantly improve the economy of the nation
- It will lower the CO₂ emission by saving the fossil fuels
- It will also reduce other airborne emission like NO_x and SO_x because most of the biomass contain less amount of nitrogen and sulphur
- It will provide energy security to the nation by producing electricity from locally available fuel like biomass
- Growing of biomass as energy crops will add value to barren lands, improve the landscapes, conserve soil resources and reduce the need for water and fertilizers

Co-firing of biomass is more cost-effective in combined heat and power (CHP) plants which generate electricity and useful thermal energy. CHP, also known as cogeneration, is often used in industrial facilities where there is specific demand for both heat and power. The economics of biomass co-firing is increased when it is used in CHP plants because of higher overall efficiency in CHP compare to normal power plants. Co-firing of biomass to the existing coal based power plants yields negative CO₂ emission to the atmosphere when it is combined with carbon capture and storage (CCS) technology.

Though, the co-firing of biomass has many advantages, it has also some disadvantages which are discussed here. Moisture content of raw biomass is high which may reduce the thermal efficiency of the plant. Ash content in biomass is also high which may lead to the ash deposition on heat exchange surfaces. Chlorine from biomass can accelerate corrosion of combustion system and flue gas cleanup components particularly at high temperature. Besides, the availability of biomass varies with season. However, there is no renewable energy source other than biomass which is chemically as fit as fossil fuel. Almost all biomass fuels can be used in coal based power plants according to the available resources near to the power station.

Power generation by co-firing of biomass to the existing coal based power plants are increasingly gaining importance because it gives the opportunity to replace our precious fossil fuels partially, which may gives extensive support to the growth of power sector. Compare to dedicated biomass based plants, the addition of biomass to the high efficiency coal-fired power plants can greatly increase the efficiency of utilizing biomass (Baxter, 2005). Besides, the cost of retrofitting an existing coal-fired power plant for biomass co-firing is significantly lower than building a new dedicated biomass based power plant (Spliethoff and Hein, 1998). Therefore, research on co-firing of coal and biomass increased considerably during the last few decades which provide very diverse solutions for biomass co-firing with a limited impact on efficiency, operation and lifespan.

This article provides a concise review on co-firing of coal and biomass. Different technical issues like co-firing types, co-firing reactors and effect of fuel characteristics are discussed in detail. In addition, the effect of co-firing of biomass on the GHG emission is also discussed.

Theory of Co-Firing

The basic idea of co-firing of biomass with coal is to replace certain amount of thermal energy input from coal with the same amount of thermal energy input from biomass. Biomass can be utilized in three different ways for providing thermal energy input to the existing coal fire plants. If biomass is combusted directly with coal then it is called direct co-firing. When biomass is converted to fuel gas in a gasifier and subsequently the fuel gas is combusted in the coal furnace then it is called in-direct co-firing. If biomass and coal are combusted in separate furnaces and generate steam separately then it is called parallel co-firing. Direct co-firing is the simplest way which requires minimal investment. But, parallel and indirect co-firing methods are more suitable for biomass materials which have issues in combustion or when the ash quality is of importance for subsequent sale or disposal. These methods of co-firing of coal and biomass are discussed in detail below.

Direct Co-Firing

In direct co-firing, combustion of coal and biomass takes place simultaneously at the same combustion chamber or furnace. Direct co-firing can be done either by pre-mixing coal and biomass and injecting the mixture to the coal handling system or directly injecting them (without physical mixing) into the pulverize coal firing system. In case of pre-mixing, coal and biomass can be mixed either before milling or after milling. In case of direct injection, coal and biomass are burned either using separate burners or combined burners depending principally on the biomass fuel characteristics. Direct co-firing is the simplest and least expensive method of co-firing. Hence, it is the most commonly applied co-firing configuration reported so far. However, the direct co-firing systems are more sensitive to variations in fuel quality and heterogeneity. Ash deposition and corrosion usually increase with the use of biomass which may shorten the lifespan of devices in contact with flue gas. Therefore, the amount of biomass which can replace the coal is limited by the type of biomass to be used. In direct co-firing, approximately 3%–5% of biomass could be co-fired with coal without significant investment costs. However, the co-firing percentage may raise upto 20% when cyclone boilers are used, although the best results are achieved with pulverized coal fires boilers (Basu *et al.*, 2011). The method of direct co-firing is shown schematically in Fig. 1. In most cases, the biomass thermal input in direct co-firing schemes is around 10% owing to technical and economic constrain (Karampinis *et al.*, 2014).

Indirect Co-Firing

In indirect co-firing system, coal and biomass are not burned in the same furnace. It is relatively complex in arrangement and expensive compare to the direct co-firing system. Indirect co-firing can be carried out in different ways. Biomass may be burned in a separate system and the flue gas is injected to the original coal boiler or burning coal and biomass in separate systems and both the systems couple their heating fluid circuits with separate exhaust gas treatment or biomass may be converted into fuel gas in a gasifier and then passing the fuel gas through the coal boiler. The most suitable gasification technology for indirect co-firing is fluidized bed gasification either in the form of bubbling fluidized bed gasification or circulating fluidized bed gasification, since they permit the use of a wide range of biomass fuels. Indirect co-firing reduces the problems associated with corrosion, fouling and slagging as the biomass is not fed directly to the furnace. Therefore, indirect co-firing system has the advantage of better fuel flexibility than direct co-firing and it also allows larger amount of biomass co-firing than direct system. Since, biomass and coal are converted separately, different conversion systems like fluidize bed system for biomass and pulverize system for coal can be used. Biomass materials which are relatively difficult to handle for combustion because of high alkali and chlorine contents can be used here because biomass and coal ashes are kept separately. A typical indirect co-firing system is shown schematically in Fig. 2.

Fig. 1 Schematic diagram of direct co-firing.

Fig. 2 Schematic diagram of indirect co-firing.

Fig. 3 Schematic diagram of parallel co-firing.

Parallel Co-Firing

In parallel co-firing, separate combustion chambers and boilers are used for coal and biomass. Steam produce by both the boilers are fed into the main power plant system where steam is upgraded to higher temperatures and pressures to give higher energy conversion efficiencies. Therefore, the fuel preparation and feeding system is physically independent here. Parallel co-firing system offers more opportunity for using higher percentages of biomass fuels compare to the direct and the indirect co-firing systems (Thompson, 2006). Here, the maximum amount of energy that can be generated from biomass will depend on the downstream infrastructure of the existing plant such as steam turbine. Like indirect co-firing, biomass ash is separated from coal ash in parallel co-firing which allows using a wide variety of biomass. However, parallel co-firing system is much more expensive than direct and indirect co-firing systems because of additional infrastructure requirement. Parallel co-firing technique is mostly used in paper and pulp industries. The schematic diagram of a typical parallel co-firing is shown in Fig. 3.

These different methods of co-firing of biomass are studied by many researchers experimentally and also implemented commercially in a number of plants. These commercial plants are mainly located in Europe and United States. However, some units are also located in Asia and Australia. Some of the commercial plants where biomass is co-combusted with coal either by direct co-firing method or by indirect co-firing method or by parallel co-firing method are listed in Table 1.

Fuel Characteristics and Their Effect on Co-Firing

Coal and biomass have different fuel properties. These differences in fuel characteristics affect the performance of the co-firing boiler. Ultimate and proximate analysis of coal and different biomass are listed in Table 2. The main differences between coal and biomass properties are listed here.

- Biomass generally contains more moisture than coal
- Biomass contains large amount of volatiles matter compare to coal

- Coal contains more fixed carbon than biomass
- Net calorific value of coal is higher than that of biomass
- Density of biomass is lower than coal
- Biomass generally contains more amount of chlorine but very less amount of sulphur
- Pyrolysis of biomass starts earlier than coal
- Biomass char contains more oxygen
- Biomass char is more porous and reactive than coal
- Biomass ash is more alkaline in nature

So, there are many differences in fuel properties which may affect the co-firing performance. Some of the important properties which affect the co-firing performance significantly are discussed below.

Effect of Moisture

Initial moisture content in biomass available from different sources may vary from 10% to 50% which restricts the application of biomass as an alternate fuel. Due to high moisture content, the energy density of biomass is less compare to coal. In order to obtain good performance of boiler and better plant efficiency, the moisture content of biomass should be in a certain range. The optimum moisture content of woody biomass is 10–15 wt% for efficient combustion. If moist biomass is used, a significant amount of heat is used to evaporate the moisture which reduces the lower heating value of the flue gas (Luk *et al.*, 2013). This heat energy cannot be utilized in the power generation process which will increase the energy input to the system for same output if moist biomass is used (Holmberg and Ahtila, 2004). Instead, if dried biomass is used, the product of combustion will result in higher flame temperature which will increase the radiant heat transfer in the boiler. Higher heat transfer will increase the steam production for the same boiler tube. With the higher flame temperature there will be more complete combustion of fuel which will reduce CO emission and less fly ash will leave the boiler. The energy efficiency of a boiler thus could be increased by replacing wet biomass with dry biomass. It is observed that maximum boiler efficiency of 74% is achievable with standard equipment while biomass with 45% moisture is used and it can reaches to 80% with the same equipment while dry biomass of approximately 10%–15% moisture is used (Ross, 2008). Therefore, it is very much important to reduce the amount of moisture in biomass before co-firing. Moisture in biomass can exist in three forms: water vapour, capillary water in the pores and bound water in the solid matrix. Drying of biomass generally occurs at about 100–200°C when water from biomass is released as vapour. However, biomass does not decompose at this temperature because the temperature is not high enough to cause any chemical reaction. Drying of biomass before co-firing has a number of advantages which include but not limited to the better energy efficiency, high combustion temperature, nearly complete combustion, better energy quality, ancillary power reduction and lower emissions (Granstrom and Javeed, 2016; Moreno *et al.*, 2006). Drying is an energy intensive process and a significant amount of energy is consumed for drying. Therefore, even though the drying of biomass provides a number of benefits, they must be balanced against increased capital and operating costs.

Effect of Ash

Ash is another important factor which has significant impact on the boiler performance. The nature of ash left after combustion depends upon the type of co-firing technology employed. For example, direct co-firing produces a mixture of coal and biomass ash and indirect/parallel co-firing produces separate coal and biomass ash (Agbor *et al.*, 2014). In general, the amount of ash produces by burning unit mass of fuel is more in case of biomass compare to coal. At high temperature (>800–1000°C), ash is fused or partially fused and deposited in the furnace refractory or water wall surfaces which may reduce the heat transfer rate in heat exchange surfaces, affect the burner operation and can damage the furnace ash hopper and other components. This high temperature ash deposition process occurs very rapidly, within few minutes or hours, is known as slag formation. Ash deposition at relatively low temperature (<1000°C) on superheater, reheater and evaporator surfaces occurs due to bondage of ash particles with relatively low melting point constituents like alkali metal. This is one of the most important ash related issues associated with the combustion of biomass with coal because biomass ash contain relatively high amount of alkali metal. The corrosion process on the gas-side surface of boiler tube occurs at high temperature underneath ash deposits. Higher amount of alkali metal and lower amount of sulphur/chlorine ratio in biomass compare to coal also have influences related to the high temperature corrosion.

Reactors for Co-Firing

There are three major types of boilers which are used for co-firing of coal and biomass i.e., grate fire boiler, pulverize fuel fire boiler and fluidize bed boiler. The grate fire boiler is the oldest technology for combustion of solid fuel. Though this technology is used in some co-firing plants but it is not very suitable for co-firing application. The pulverize fuel fire boilers are the mostly used boilers for combustion of coal. However, pulverize fuel fire boilers are also used for co-firing of coal and biomass. The fluidize bed boilers are the most preferred technology for co-firing of coal and biomass due to its advantageous feature of fuel flexibility. Under this section, three different types of boilers, their working principles, advantages, disadvantages and their applications are discussed below.

Fluidize Bed Boiler

Fluidization is the operation by which a bed of solid particles is converted into a fluid like state by forcing a gas through it. As the gas velocity is increased, a situation arrives when solid particles are just suspended by the gas and the situation is called the minimum fluidization condition. After increasing the gas velocity beyond the minimum fluidization velocity, bubble formation starts from the bottom. Bubbles grow in size while travelling through the bed by coalescing small bubbles and finally burst at the upper surface of the bed and particles are splashed into freeboard region. This is called bubbling fluidized bed (BFB) boiler or combustor. Fig. 4 shows the schematic representation of a bubbling fluidized bed boiler. If the velocity of gas is increased beyond the bubbling fluidized bed, solid particles are distributed across the whole riser height, bigger particles fall back and smaller particles are entrained by the gas. These entrained particles are separated from the gas with the help of cyclone separator and fed

Fig. 4 Bubbling fluidize bed boiler.

Fig. 5 Circulating fluidize bed boiler.

back to the bed with the help of loop-seal/L-valve. This is called circulating fluidized bed (CFB) boiler or combustor. Fig. 5 shows the schematic representation of a circulating fluidized bed boiler. In CFB combustor the bed and the freeboard regions are no longer separated. The main advantage of fluidized bed boilers is its fuel flexibility in terms of use of different types of fuel, feed rate, particle size and moisture content. Therefore, the fluidised bed boilers designed for coal combustion can also be converted for co-firing of coal and biomass with small retrofitting. The typical fluidization velocity in a bubbling fluidised bed combustor is 1–2 m/s which is about 5–10 m/s for circulating fluidised bed combustor (Loha *et al.*, 2018). In a fluidized bed combustor, it is possible to achieve the fuel-to-steam efficiency over 90% even with low grade fuels. Because of the high amount re-circulation of bed material in CFB, it is possible to burn moist, heterogeneous fuels with low calorific value. However, a support fuel can be used for high moisture content fuels. In fluidized bed combustors, more than 90% of the bed is occupied by sand/ash and the rest is fuel which balances any changes in fuel quality/moisture and prevents combustion disturbances and undesired bed temperature variation. The choice between BFB and CFB technology largely depends upon the plant capacity. BFBs are generally preferred for small scale application upto 20 MWth, whereas, CFBs are preferred for large-scale applications of more than 30 MWth. At this juncture, fluidised bed combustors are the best combustion systems available for co-firing of coal and biomass because of fuel flexibility, high rate of heat and mass transfer and lower emission due to low temperature combustion.

Pulverize Fuel-Fire Boiler

Pulverize fuel combustion is the most commonly used method for combustion of coal. However, it is also used for co-firing of coal and biomass. Here coal and biomass are grounded to fine powder and pneumatically injected into the furnace. Pulverize fuels are blown into the boiler plant through a series of burner with the help of a part of combustion air called primary air. The fuel is burned

by injecting secondary and tertiary air. Air is also injected downstream from the burner to reduce NO_x. Based on the boiler capacity and the capacity of each burner, a number of burners are used. The combustion is initiated with the help of an auxiliary burner. As the combustion temperature reaches a certain value, the auxiliary burner is shut down and the fuel is injected. The residence time of fuel particles in a pulverize fuel fire boiler is typically 2–5 s. Therefore, the particle size needs to be very small ($\sim 100 \mu\text{m}$) so that complete combustion takes place within this time. Due to small particle size and high gas velocities, the ash is mostly carried with the flue gas and is partly precipitated in the post-combustion chamber. Fig. 6 shows the schematic of a pulverized fuel fire boiler. The quality of fuel used for pulverize combustion need to be quite constant. The moisture content of the fuel should not be more than 20% (wb). The capacity of pulverize boiler may be as high as to meet the demands of the steam turbines with outputs 500–700 MWe.

Grate Fire Boiler

Grate fired boiler is the oldest amongst different type of boilers used for solid fuel combustion. Though the grate fire boilers are also used for co-firing of coal and biomass but they are not very common. The construction of grate fire boiler is simpler than pulverize fuel fire boiler and fluidize bed boiler. There are different types of grate fire boiler which are used e.g., fix flat grate, fix sloping grate, mechanical sloping grate and chain grate. The efficiency of grate fire boiler is lower and the flue gas emission is higher compared to pulverize fuel fire boiler and fluidized bed boiler. It also required fuel with uniform size and quality. Fig. 7 shows the schematic of a grate fire boiler.

Effect of Co-Firing on the Greenhouse Gas (GHG) Emissions

CO₂ is the major contributor to the global atmospheric Greenhouse Gas (GHG) emissions. This is because CO₂ has a very high residence time in the atmosphere. CO₂ released from fossil fuel combustion might be presents in the atmosphere upto 300 years.

Fig. 6 Pulverized fuel-fire boiler.

Fig. 7 Grate fire boiler.

In addition 25% of them lasts forever (Adanez *et al.*, 2012). Hence it is the most important anthropogenic greenhouse gases of our concern. The Global atmospheric concentration of CO₂ has increased to 408 ppm in 2018 (Trends in atmospheric CO₂, 2018). The concentration of CO₂ increased every year since scientists started measuring the slopes of the Mauna Loa volcano more than five decades ago. The rate of increase has accelerated from about 0.7 ppm per year in the late 1950s to 2.1 ppm per year during the last decade and now the rate of increase is 100 times faster than the increase that occurred when the last ice age ended. Therefore, it is felt worldwide that reduction of atmospheric GHGs is essential as soon as possible.

Co-firing of biomass in coal fired power plants offers the simplest and cost effective way to reduce greenhouse gas (GHG) emissions. This is because the co-firing of biomass to the existing power plant can be done by minimum retrofitting and the cost associated with the retrofitting is less compared to the other option available for GHG reduction. The CO₂ emission from a coal fired power plant of identical capacity reduces while biomass is co-fired with coal because biomass does not add net CO₂ to the atmosphere owing to the fact that the combustion of biomass releases the same amount of CO₂ which it absorbs during growing. It is estimated that the CO₂ emission could be reduced by 45–450 million tons per year in 2035 if 1%–10% of coal in power plants is replaced by biomass assuming an average CO₂ emission level of 95 kg/GJ from coal combustion (van der Hoeven, 2011).

There are three different routes of NO_x formation; thermal NO_x, prompt NO_x and fuel NO_x. Thermal NO_x is generated at high temperatures from nitrogen present in combustion air. Prompt NO_x is generally formed in rich combustion region through an intermediate species generated from decomposition process of hydrocarbon fuels. Prompt NO_x is formed in the presence of hydrocarbons and fuel NO_x is originated from fuel-bound nitrogen. In most of the combustion cases NO accounts for about 90% of the total NO_x. Reduction of NO_x emission from co-firing of biomass with coal depends upon biomass type, reactor type and operating condition (Baxter, 2005). It is observed that most of the fuel nitrogen in biomass is converted to mainly NH₃ during combustion and NH₃ reduces NO to molecular nitrogen which is one of the reasons reported for the reduction of NO_x emission in co-firing of biomass (Hughes, 2000). Another reason for reduction of NO_x in co-firing of biomass with coal is the quick release of volatiles in biomass particularly in the lower part of the reactor which produces a lot of radicals which consume local oxygen and also de-oxidized NO_x. It is observed that biomass derived from forest residues have a lower tendency because they contain less nitrogen to produce NO_x compared to biomass derived from agricultural residues (Agbor *et al.*, 2014). Lower combustion temperature in fluidised bed boiler compared to pulverized fuel fired boiler reduces the formation of thermal NO_x. However, N₂O emissions seem to be higher in fluidised bed boiler.

Co-firing of biomass also reduces the emission of SO_x because of mainly two reasons. Firstly, most of the biomass contains very less amount of sulphur compared to coal and additionally, due to the retention of sulphur in the ash generally presents in the form of solid alkali sulphates.

Use of biomass residues for co-firing will also gives additional greenhouse gas reduction because these biomass materials will otherwise be used for land filling which will release CH₄ which have 21 times more global warming potential than CO₂ (Hughes, 2000).

However, the emission of particulate matter from combustion of biomass required attention particularly in small-scale power plants with low-efficient particulate filters, which traps fine particles.

Different Biomass Sources for Co-Firing

Biomass available from different sources can be utilized for co-firing. Available biomass resources for co-firing may vary from country to country. However, they can broadly be classified into three groups as wood and wood residues, forest residues and agricultural crop residues.

Wood and wood waste: Wood is the main source of biomass energy in many countries. Wood residues include bark, sawdust, wood chips and wood scrap from wood industries.

Forest residues: Forest harvesting is a major source of biomass for energy. Harvesting may occur as thinning in young stands or cutting in older stands for timber or pulp that also yields tops and branches may serve as potential biomass for co-firing.

Agricultural crop residues: Large quantities of crop residues such as husk, straw, stem, stalk, leaves, shell, pulp etc. are produced which are mostly underutilised could be the potential biomass resource for energy generation.

Different agricultural crops available from major biomass producing countries which can potentially be utilized for co-firing are shown in Table 3.

Future of Co-Firing

Though the co-firing of biomass to the existing coal fire power plants seems to be one of the most efficient and environment friendly option to exploit biomass for energy generation but its future application will depends mostly on the following points.

- It will largely depend on the overall sustainability of biomass. Enough supply of biomass should be ensured to meet the targeted level of biomass co-firing. For this there is an urgent need to assure the ecologically sustainable biomass production. This calls for further technology development, process and infrastructure development to produce/collect more biomass. Subsidies and incentive should be provided to grow biomass in barren lands to fulfil the requirement. It is also required to

Table 3 Potential agricultural crop from major biomass producing countries

Country	Agricultural crops
Australia	Wheat, Rice, Sugarcane, Grape, Agave, Canola, Giant reed, Sorghum
Bangladesh	Rice, Wheat, Pulses, Oil seeds, Tobacco, Sugarcane, Jute, Maize, Barley, Sorghum, Millet
Brazil	Sugarcane, Bamboo, Eucalyptus, Sisal, Wheat, Barley, Oats, Maize
Canada	Corn, Wheat, Straw, Switchgrass, Canola and Sunflower
China	Bamboo, Rice, Bagasse, Rapeseed, Sumac, Chinese goldthread, Sweet broomcorn
Ethiopia	Maize, Coffee, Sorghum, Sugarcane, Wheat, Millet, Barley
Germany	Sugarcane, Rapeseed, Sunflower, Palm, Maize, Wheat
India	Rice, Wheat, Cotton, Sugarcane, Jowar, Bajra, Maize, Coconut, Cashewnut, Groundnut, Banana
Italy	Straw, Pruning, Forestry, Vinasse, Olive, Fruit Shell, Rice
Malaysia	Rubber, Rice, Coconut, Cocoa, Palm
Nigeria	Sugarcane, Cassava, Sorghum, Maize, Oil, Palm, Soybeans, Millet, Cocoa, Coffee, Groundnut, Rice, Cotton, Tobacco, Wheat
Russia	Wheat, Rapeseed, Soybean, Sunflower
South Africa	Sugarcane, Maize, Sorghum, Sweet Sorghum, Soybeans, Groundnuts, Sunflower
Tanzania	Cotton, Sugarcane, Cashew nut, Maize, Cassava, Banana, Sweet potatoes, Groundnut, Sunflower, Simsim
Thailand	Rice, Sugarcane, Corn, Cassava, Palm, Jatropha
UK	Straw, Cereal, Oil crop, Sugarcane, Eucalyptus, Miscanthus, Willow
USA	Corn, Wheat, Sunflower, Corn, Palm, Switchgrass, Miscanthus, Poplar, Willow

identify the appropriate biomass which has the highest potential of sustainable supply depending on economic and geographical factors.

- Cost of biomass will play an important role for the future application of biomass co-firing. Even though the raw material cost is low but the availability of biomass is so diversifier that the cost of collection and transportation become the major issue.
- It is required to develop properly organized biomass market so that every coal fired power plants can take advantage of it.
- Spreading of biomass co-firing technology will depend on the amount of incentive given for reduction of CO₂. It will attract the investors to establish such technology in future.
- Public awareness on environmental pollution and the use of renewable energy will also force to advance the biomass co-firing technology.
- Last but not the least, it will also largely depends on the policy of the individual country like how the country will set their target and what type of promotional scheme they will take to implement it. For example, to promote biomass co-firing the country may decide certain percentage of co-firing mandatory in the existing and upcoming coal based power plants.

Conclusion

This work highlights the contributions of co-firing of biomass with coal in reducing the emissions of greenhouse gases like CO₂, NO₂ and SO_x. Co-firing of biomass in existing coal based power plants is considered as the simplest, most effective and economical short term solution to conserve fossil fuel, increase the use of biomass and reduce net CO₂ emission. Hence, the importance of co-firing of biomass with coal is increasing day-by-day throughout the world. The three different methods of co-firing of biomass namely direct co-firing, indirect co-firing and parallel co-firing are discussed. Direct co-firing is the simplest and most commonly used method which requires minimal investment although the amount of biomass share is limited in direct co-firing. Whereas, indirect and parallel co-firing methods are comparatively complex albeit they are more suitable for biomass fuels containing problematic compounds or when the ash quality is of importance for subsequent sale or disposal. Co-firing of coal and biomass is studied in different types of boilers and it is observed that fluidized bed boiler is most suitable because of its advantageous features like fuel flexibility and low temperature combustion.

Introduction

The quality of human life depends largely on accessibility of energy, eventually; world energy consumption is rising every day. The source of power production in general is mostly from coal. As a consequence, the thermoelectric produced by burning of coal results in tons of carbon dioxide (CO₂) to environment which remarkably increases the *carbon footprint*. Carbon foot print is basically defined as total emissions caused by an event/organization/individual or product as carbon dioxide equivalent. The impact of an energy technology on the climate can be characterized by its carbon emission intensity, a measure of the amount of CO₂ or CO₂ equivalent emitted per unit of energy generated. Here, 'CO₂ equivalent' (CO_{2eq}) refers to non-CO₂ GHGs, notably methane and nitrous oxide, which are released from a number of human activities such as fossil fuel extraction and agriculture. Existing fossil fuel technologies possess large carbon emission intensity through the combustion of carbon rich fuels. Moreover, the amount of emitted CO₂ from thermoelectric plants is higher than produced from transportation or industrial processes. As a consequence of elevated level of greenhouse gases like CO₂, global warming index is rising day by day which badly affects our environment and ecosystem as well.

One of the protective steps against global warming is to minimize the *carbon footprint* along with mitigation of greenhouse gases (GHGs). Several countries have decided different memorandum towards this process. One of the significant processes is utilization of renewable energy like solar energy to limit the scale of future climate risks from fossil fuel use. In such ways, solar energy, along with other low-carbon assisted renewable technologies, plays a vital role in reducing the GHGs and carbon footprint from the environment especially in power sectors. Hence solar energy may help to reduce the carbon foot print by replacing more carbon intensive sources of energy. These consequences have motivated the researchers worldwide to utilize solar energy in terms of different processes. With increasing exhaustion of fossil fuels, attention is being paid to solar energy which supplies average 1.73×10^{17} J of energy to the Earth (Kopp and Lean, 2011) every second, nearly 10^4 times higher than what civilization requires. This renewable energy is also apt for enabling low carbon development in developing or under developed countries, where approximately 1.3 billion people lack access to electricity (World Energy Outlook, International Energy Agency, 2012). In that perspective solar energy is considered one of the most positive ways to decrease the climate change resulting from the use of fossil resources for energy generation.

Origin of Photovoltaic Cell

Technology of the photovoltaic cells actually started back nearly over 160 years. The fundamental science was first exposed in 1839 but the pace of advancement actually accelerated in three major thrusts in the 20th century (see "Relevant Websites section"). The scientific breakthroughs are highlighted in Table 1.

It was not until Albert Einstein wrote his paper in 1905 on the photoelectric effect: "*On a Heuristic Viewpoint Concerning the Production and Transformation of Light*" which was supported by experimentation done by Robert Millikan in 1916. Later on Einstein got Nobel Prize for this concept of photoelectric effect, in 1922. This work created the theoretical basis for all photovoltaic devices, in which photons generally excite the valence electrons out of the valence band and thrives into the higher energy conduction band, where they are collected and transported to the outer circuit. The work of Goldmann and Brodsky (carried out in 1914) was then studied in detail by many researchers, such as Neville Mott and Walter Schottky, in the 1930s. In the year of 1941 Russell Ohl devised a silicon solar cell. With the advancement of silicon in the 1950s, Fuller developed near-surface p-n junctions using a boron tri-chloride incorporation of n-type silicon, which developed charge separation in the device. In 1954, Bell Laboratories exhibited first high-power silicon PV cell with efficiencies exceeding ~6%. However, the possibilities of sensitization were not fully recognized until the early 1960s. Many new research outcomes were reported at the International Conference on Photosensitization of Solids held in Chicago, such as the sensitization of ZnO with cyanine dyes and the necessity of a mono layer dye to get maximum efficiency. Various types of p-n junctions were developed using gallium-arsenide (Ga-As), cadmium-sulfide (Cd-S), cadmium telluride (Cd-Te) and indium-phosphide (In-P). But these systems are very much expensive as well as their applications are also limited (like space applications). The term "*first*

Table 1 Scientific breakthrough at a glance

Year	Scientific breakthrough
1839	French physicist Alexandre Edmond Becquerel observed a physical phenomenon allowing light-electricity conversion when experimenting with metal electrodes and electrolyte
1883	Charles Fritts , an American inventor, described the first solar cells made selenium and thin layer of gold.
1888	Edward Weston received first US patent for “solar cell”
1901	Nikola Tesla received US patent for “method of utilizing, and apparatus for the utilization of, radiant energy”

generation” generally refers to p-n junction photo voltaics, which are made of mono-and poly-crystalline silicon, doped with other elements. Both mono and poly-crystalline photo-voltaics require complicated fabrication procedure and large amounts of silicon. First generation cells, based on single (mono) crystalline silicon, recorded the highest efficiencies of all PV devices. However, these cells comprise complicated compositions and high manufacturing costs. From 1954 to 1960, Hoffman invented a method to increase PV cell efficiency from ~2% to ~14%. In the following years, dye-sensitization was proved to be efficient due to its potential applicability in transfer of electrons or energy. The idea of using dispersed particles to offer a sufficient interface was used to develop efficient semiconductor metals, such as TiO₂ and ZnO etc. Titanium dioxide became the preferred nano-crystalline semiconductor of choice for the researchers due to its advantages like widely accessible, inexpensive, non-toxic and biocompatible. In the mid-1970s, solar cells engrossed considerable attention towards an alternative energy source. Second-generation photo-voltaic cells were developed during this period, these cells are comprised of thin-film of photovoltaic cells that are composed of amorphous poly-crystalline semiconductors. Historically, amorphous silicon (Si), cadmium telluride (CdTe), and copper indium gallium selenite (CIGS), and recently thin-film poly crystalline silicon, have been considered as prime features for thin films, of which CdTe thin film technology is the most expensive. These three types of thin-film cell structures include either mono or single junction/double or twin junction/multiple junctions. The main difference between these structures is the number of p-i-n junction layers. Depositing small thin layers of developed material with different band gaps enhances cell efficiency where as the cost of fabrication increases due to the several steps involved in depositing each layer of material during fabrication. However, the efficiency of these developed cells is lesser compared to the efficiency of wafer-based silicon solar cells, which are currently dominating the commercial PV market. Researchers throughout the world have been trying to develop thin-film devices that are very efficient as well as cost effective. First and second generation PV devices are basically fabricated from semiconductor materials. The design and development of low-cost PV cells has been the topic of interest over the last three decades. Third-generation PV cell technologies are superior compared to the first and second generation technologies by optimizing the efficiency and considerably decreasing the production costs. Most third-generation solar cells are still in the progress stage and tend to contain dye-sensitized solar cells, hetero junction cells, polymer solar cells, quantum dot cells and hot carrier cells. DSSCs are novel devices that adapt visible light into electricity based on wide band gap semiconductor sensitization and belong to a assembly of thin-film cells. The development of DSSCs began in 1972 with the invention of a chlorophyll-sensitized zinc oxide (ZnO) electrode. The group of Carlson and Pankove first invented the amorphous silicon solar cell with an efficiency of 2.4% in 1976; later efficiency was enhanced to 4%. In the subsequent years, DSSCs became an attractive subject of research from both applied and fundamental perspectives. The main problem was that a mono layer of dye molecules on surface absorbs only 1% of incident sunlight. In 1990, at the Ecole Polytechnique Federale de Lausanna (EPFL), Grätzel *et al.* succeeded in fabricating a new type of solar cell that is known as DSSC or Grätzel cell, this cell mimics photosynthesis procedure in plants by sensitizing nano-particulate titanium dioxide (TiO₂) films with a novel ruthenium (Ru) bipyridyl complex. The performance of a DSSC depends primarily on the dye sensitizer. The dye absorption spectrum and the attachment to the surface of the semiconductor (TiO₂) are key parameter for determining the DSSC efficiency. Currently, silicon made inorganic solid-state junction devices, govern the photovoltaic industry due to their cell efficiency. However, the supremacy of solid-state junction devices is now being challenged by the appearance of DSSCs. These conducting thin films and nano-crystalline material based devices can potentially replace conventional solid-state devices. The efficiency of DSSCs comprised of Ru-compounds adsorbed on nano-crystalline TiO₂ semiconductors has remarkably reached ~11%–12%.

Solar Cells

The term “solar cell” is used to refer to a cell that produces electricity from sunlight. Sunlight is essentially the radiation spectrum of a 5800 K black body with differences due to spectral lines and absorption. Cells can be described as photovoltaic or solar cells even when the light source is artificial one. There are mainly two types of solar cells: (i) solid-state devices and (ii) liquid electrochemical cells. The mechanism of all photo voltaic cells may be elucidated in two steps: (i) light absorption followed by electronic excitation and (ii) charge separation and transport of electrons (Bisquert and Vikhrenko, 2004). These actions are accomplished with different pathways in solid-state and electrochemical cells, although the results are the same in both cases. A better concept of dye-sensitized solar cells can be gained through discussions of these different types of photovoltaic cells (Sze and Ng Kwok, 2007).

Fig. 1 (a) Schematic diagram of diffusion establishing a “built-in” electric field and (b) the transfer of electrons and holes due to diffusion and the “built-in” electric field.

Silicon Solar Cells

Being the 2nd most plentiful metal in the Earth’s crust, silicon has the advantages of being inexpensive as well as easily available in adequate quantities. Moreover its manufacturing processes are eco-friendly (El-Refi, 2014). The concept of standard silicon solar cell is based on a semiconductor p-n junction. Homo-junction solar cells, like conventional silicon solar cells, have both p-type and n-type semiconductors comprising of the same material, whereas hetero-junction solar cells, like thin-film solar cells are made of cadmium telluride or dye-sensitized solar cells have n-type and p-type semiconductors comprising of different materials. n-type semiconductors are developed through the doping of pentavalent impurity atoms, such as arsenic, phosphorus and antimony, which share free electrons and thereby remarkably increase the conductivity of silicon. The addition of tri-valent impurity atoms, such as boron, aluminum and gallium, which have one lesser valence electron than the silicon atoms, generates p-type semiconductors (McEvoy *et al.*, 2003). **Fig. 1(a)** shows a schematic of silicon cells, which are simply silicon (semiconductor) p–n junctions. When n- and p-type semiconductors are combined, large density gradients form between the sides of the p-n junction as a result free electrons from the n-type silicon impurity atoms (donors) begin to migrate across this newly developed junction to fill the holes in the p-type silicon (acceptor), which generates negative ions. The movement of electrons across the p-n junction from the n-type to the p-type leaves positively charged phosphorous ions on the negative side, while the holes migrate from the p-type acceptor to the n-type region across the p-n junction, where there are many free electrons, leaving the negatively charged boron ions behind. Due to this drive of electrons, the charge density of the p-type conductor along the p-n junction is filled with negative charges, and the charge density of the n-type silicon conductor becomes positive. The free electrons and holes are affected by the built-in electric field, as result the negative electrons are attracted towards the positive phosphorus centers and positive holes are attracted towards the negative boron centres. This transfer of electrons and positive holes across the p-n junction is termed as diffusion. The movement of electrons and holes across the p-n junction occurs until equilibrium (an electrically neutral condition) is attained. At equilibrium, no net charge diffusion occurs, and a depletion region is formed (**Fig. 1(b)**), which is also referred to as a space charge layer. This incident is known as the equalization of the Fermi energy level in the materials. The depletion region becomes highly resistive and acts as crystalline silicone, which is almost like an insulator. By the incorporation of an external electric field to the previous built-in electric field, the resistance of the depletion layer may be customized. At the p-n junction, solar energy absorbed by the semiconductor silicon will dislodge an electron and create an extra mobile electron and an extra mobile hole. The electron field assures the electron flow to the n-type material and the hole flow to the p-type material. This process is known as the *photo generation of charge carriers*, which occurs throughout n-type and p-type semiconductors. The resulting separation of the positive and negative charges across the p-n junction is named as voltage or potential difference. Preplanned connection of a solar cell to an external circuit allows both electrons and holes to travel around the circuit and recombine, which returns the system to its primary condition (**Fig. 2**). Interestingly if positive voltage is applied on n-type cell and negative voltage is applied on p-type cell, there will be no current flow. The resistance in a silicone cell is large at voltages nearly from 0 to 0.6 V due to depletion region, while the resistance is very small at voltages exceeding 0.6V and there will be current flow without any constraint (Gregg and Hanna, 2003).

Dye-Sensitized Solar Cells

The development of photovoltaic cells for the last two decades led to the development of devices that are cost effective and expands the applications of photovoltaic cells to compete with other energy production systems. These technologies are taken as emerging photovoltaics. The use of dye sensitization was limited, rather unsuccessful until 1991, when Grätzel and his co-workers successfully developed a solar cell by successful recombination of nano-structured electrodes with efficient charge donating dyes at the Laboratory of Photonic and Interfaces in the École Polytechnique Fédérale de Lausanne in Switzerland. DSSCs are devices that

Fig. 2 Schematic diagram of the motion of mobile electrons and holes due to diffusion and the “built-in” electric field.

can convert solar energy to electric energy by light sensitization established on wide energy band semiconductor. Now a days DSSCs have shown a very promising future in the field of photovoltaic cells. These solar cells (DSSCs) differ from other solar cell related devices in their basic constructional and operational point of view. In contrast to first and second-generation PV devices, which are based on solid-state semiconductor materials, the typical arrangement of DSSC combines both solid and liquid phases. Dyes used in solar cells are classified into two broad categories i.e., organic and inorganic dye. Ruthenium (Ru) dyes are presently known to be the most significant inorganic dye for the fabrication of DSSCs with great efficiency.

DSSC Structure

A DSSC is a complex system for light-to-electricity conversion. The basic structure of a DSSC is similar to the original design made by Grätzel *et al.* Economic as well as environmentally friendly properties of dye-sensitized solar cells (DSSC) make the DSSCs one of the most promising classes of photovoltaic cells for the conversion of photon energy to electricity. In general, DSSC contains of a working counter electrode, a redox-coupled electrolyte containing iodide and tri-iodide ions, and a porous semiconductor electrode-absorbed dye of nano-crystalline nature. The dye molecule of the DSSC plays a pivotal role in absorbing sunlight and in the conversion of solar power to electrical energy. The operational mechanism of DSSCs are based on the photo-sensitization created by the dyes on wide band-gap mesoporous metal oxide semiconductors. As a consequence, with time, DSSCs have become more interesting since large collections of dye including natural dye can be used as light harvesting elements to deliver the charge carriers. This review brings the history of DSSC with a focus on the recent advancements of the Ru-dyes in this specific area, the working principle of DSSCs as well as the work done over recent the years on Ru-dye based DSSCs. Apart from DSSC's advantages, there are several disadvantages as well. Efficiency of DSSC is one of the major concerns. The majority of low efficiencies are due to traditional photo-sensitizers undergoing low absorption, narrow absorption spectra along with the loss of energy absorbed by the electrolyte. For this reason, an approach using co-sensitization was investigated to recover the performance of the DSSC. Several research works have been targeted towards the improvement of new and efficient photo-sensitizers, including sensitizers like ruthenium complexes, zinc porphyrins as well as metal-free organic dyes. Ruthenium based sensitizers such as the N3, N719 and black dye etc., were rigorously tested as light harvesters and reached up to a remarkable milestone where overall power conversion efficiency is in the range of $\sim 11\%$ under Air Mass 1.5 (AM 1.5) irradiation while organic photo sensitizers have reached power conversion efficiency (PCE) in the range of $5\text{--}8\%$. As of now, metal-free indoline dye (D149) is the most effective photosensitizer for DSSCs and has attained very high efficiencies up to 9% . Recently, devices are fabricated by using Ru^{II} complexes with $\text{Co}^{\text{III/II}}$ based electrolytes have achieved efficiencies up to 9.4% . Overall a schematic diagram is given based on the successful implementation of the three kind of dyes i.e., Ru-dyes, metal free dyes and natural dyes.

From the graph (Fig. 3) it is observed that, there is a steady progress in Ru-based dyes since 1991 and a maximum efficiency of 13% is achieved in the year 2014. Metal free dyes and organic dyes, on the other hand have started its growth from the year 2004. But the efficiency is very less compared to the Ru-based dyes. A maximum of 10.7% efficiency was reported in the year 2010 which is still lesser than Ru-DSSC. Moreover, the performance of the Ru-complexes based on the conversion yield and long term thermal stability is admirable compared to other dyes. There are huge opportunities regarding further development of the DSSCs in domain of repeatability and reliability of the sensitizers.

In a nutshell continuous development in this DSSC field explores the potential implementation of solar photovoltaic (PV) technologies to deliver rapid transformation of our energy systems to limit the scale of future climate risks from fossil fuel use. In particular, cost reductions, scalability of manufacture and the new science needed are to be kept in mind in order to accelerate the uptake of solar power technologies. Low carbon foot print forecasts that by 2050 some $14\text{--}22\%$ (IEA_{2DS} base Scenario, 2012) or more (Greenpeace International, European Renewable Energy Council, Council GWE, 2012) of electric power should be supplied by solar conversion. In such pathways, solar, along with other low-carbon technologies will play a vital role in decarbonizing the power sector.

Fig. 3 Plot of progress in efficiency (η) of DSSC up to 2014 based on three different types of sensitizers: Ru-based DSSC, metal free DSSC and natural DSSC.

Characteristics of DSSC

The performance of DSSCs is monitored by two main criterions, i.e., (i) overall efficiency (ii) photochemical as well as thermal stability. Other required parameters are IPCE (Incident Photon to Current Conversion Efficiency also known as Quantum efficiency), I_{sc} (short-circuit current i.e., when the voltage across the solar cell is zero (i.e., when the solar cell is short circuited)), V_{oc} (open circuit voltage i.e., Open Voltage Current is the maximum voltage available from a solar cell and this occurs at zero current), FF (fill factor i.e., the ratio of the maximum power from the actual solar cell to the maximum power from an ideal solar cell). The efficiency of DSSC is remarkably dependent on the following factors:

- (1) The ratio of input energy from the sun to solar cell and the energy output from the solar cell.
- (2) Photovoltaic device should have a serviceable life-time of about 20 years without substantial loss of performance. Efficient dyes like N3 sustained 108 cycles after long time illumination.
- (3) Regeneration is another prime factor here, and it should happen fast to maintain the long term stability of the cell. Common tests are based on 1000 h stability tests at 80°C for evaluating the photochemical stability of the DSSC.

Mechanistic Pathway

The dye-sensitized solar cells are generally comprised of five components: (i) Transparent Conductive Oxide coated a mechanical support; (ii) the semiconductor film, usually TiO_2 ; (iii) a sensitizer adsorbed onto the surface of the semiconductor; (iv) an electrolyte containing a redox mediator; (v) platine like counter electrode capable of regenerating the redox mediator. The Schematic representation is given below (Fig. 4).

The basic operating principle for any DSSC contains absorption, separation and collection. Different types of optimization of these parameters take DSSC to attain better efficiency. Thus, absorption occurs in the very first step of the reactions occurring in the solar cell. Under illumination, sensitizer dye (A) absorbs a photon that may lead to excited sensitizer state (A^*). Photo excitation of this sensitizer is then followed by the electron insertion into the conduction band of the semiconductor (generally mesoporous). This leads sensitizer to an oxidized state A^+ with electron donation from the electrolyte but the original state of the dye restored. Iodide/triiodide system is widely used in DSSC as redox couple for regeneration of the dye. Here, Iodide regenerates the sensitizer, and gets itself reproduced due to the reduction of triiodide at the counter electrode. In this way, the circuit gets completed by transfer of electron via the external load. The following reactions summarize the working mechanism (Gratzel, 2003; Nazeeruddin *et al.*, 2011)

Factors Affecting Absorption Spectrum

Concentration of the dye within the nano-porous TiO_2 surface and the absorption coefficient determines the fraction of light that will be absorbed by the TiO_2 layer. A sensitizer should have

Fig. 4 Schematic diagram of dye-sensitized solar cell.

- (1) high absorption coefficient in the visible region and
- (2) high affinity to the TiO_2 surface in order to ensure a dense coverage of the surface. Also increase in absorbance helps in reducing the thickness of the TiO_2 layer thereby eliminating the probability of recombination.

Generally at longer wavelengths, the absorption decreases significantly, thus a substantial fraction of the solar spectrum will be lost. The absorption of the dye can be described with Beer-Lambert's Law (Eq. (5))

$$\frac{I(x)}{I_0} = 10^{-\alpha(\lambda) \cdot x \cdot C_{\text{dye}}} \quad (5)$$

where $I(x)$ is the light intensity at the point x (W m^{-2})

I_0 is the initial light intensity (W m^{-2}).

α is the absorption coefficient ($\text{M}^{-1} \text{cm}^{-1}$).

λ is the wavelength (nm).

C_{dye} is the concentration of the dye (M).

x is the path length (cm).

Apart from TiO_2 , ZnO and Nb_2O_5 have also been investigated for the use of semiconductor. Sensitizers are mostly metal complex dyes and are formed as a dye. Although a lot of dyes have been studied including natural dyes, Ruthenium complexes have proved to be the most effective due to its photon to current conversion efficiency as well as its thermal efficiency over a wide range of temperature.

Sensitizers

Sensitizer is a very crucial part of the DSSC and it possess some essential characteristics. The ideal sensitizer for a single junction PV cell converting standard global Air mass (AM) 1.5 sunlight to electricity should absorb all light below a threshold wavelength (~ 920 nm). Moreover, it must be grafted on the semiconductor oxide surface with the assistance of attachment groups like carboxylate or phosphonate. The attachment group of the dye confirms that it spontaneously gathers as a molecular layer after exposing the oxide film to a dye solution. It will make a high prospect that after a photon is absorbed, the excited state of the dye will relax back to its ground state by electron injection to the semiconductor conduction band. It should insert electrons after proper excitation and its energy level must match with the lower bound of the conduction band to avoid any kind of energy loss. It should be rapidly regenerated and be fairly stable, both in the ground and excited states. Also, it must be stable enough to bear about 10^8 turnover cycles. Many different compounds have been examined for semiconductor sensitization, such as porphyrins, coumarin, phthalocyanines, carboxylate derivatives of anthracene and other type of polymeric films. Among the photo-sensitizers studied, transition metal complexes have been the best till date. Photovoltaic performances can be assessed based on conversion yield and long term stability of the dye. Interestingly the polypyridyl complexes of Ruthenium have fulfilled both the criterion. The general structure which is proven best for sensitizers is $\text{ML}_2(\text{X})_2$, where M may be a metal like Ru and L is 2,2'-bipyridyl-4,4' - dicarboxylic acid and X presents a halide, cyanide, thiocyanate, thiocarbamate etc. (Scheme 1).

The present review is based on the current research issues in the field of a new dye sensitized solar cell based on charged electron injection from molecular sensitizers into a semiconductor oxide having wide-band-gap of nanocrystalline morphology. Some discussions based on some Ru-complexes, their properties and the principles of solar light energy harvesting and conversion to electric power are done by these systems.

Ru-Complex Dyes

In the year of 1991, Ru-based DSSC exhibited a remarkable success with a conversion efficiency of 7.1%. Ru (II) metal is always an excellent choice for a number of reasons: (1) its octahedral geometrical structure that tolerates extending of specific ligands in a controlled fashion; (2) the photo physical, photochemical and electrochemical properties of Ru (II) complexes can be tuned; (3) it possesses multiple stable and accessible oxidation states from I to IV; (4) possess good solubility in many solvents.

Scheme 1 Schematic operating principles and energy level diagram of DSSC.

Scheme 2 Post synthetic route for the Ru-dye preparation.

Nazeeruddin *et al.* (1993) prepared *cis*- $X_2\text{Bis}(2,2'\text{-bipyridyl-4,4' dicarboxylate})\text{ruthenium(II)}$ complexes ($X = \text{Cl}^-, \text{Br}^-, \text{I}^-, \text{CN}^-$, and SCN^-) and characterized by absorption, luminescence, and redox behavior. These complexes act as very efficient charge transfer sensitizer materials for nanocrystalline TiO_2 films (thickness of film about $\sim 8\text{--}12\ \mu\text{m}$). The thiocyanato derivative *cis*-di(thiocyanato)-*bis*(2,2'-bipyridyl-4,4' dicarboxylate)ruthenium(II) was found to exhibit excellent properties, taking it as a very striking new redox sensitizer compared to other known sensitizer. The four carboxylate groups attached to the two bipyridyl moieties assure rigid adsorption onto the surface of oxides such as TiO_2 . Apart from this, carboxylate groups also provide strong coupling between the two predominating factors i.e., charge-transfer excited state and the conduction band wave function of the semiconductor. As a consequence, ultrafast electron flow from the excited complex into the semiconductor occurs at nearly 100% quantum yield. A solar-to-electric energy conversion efficiency of 10% was gained with this system. The effect of temperature on the power output and the thermal stability of the dye was also examined. It has been claimed that a device based on a simple molecular light absorber module has been designed which attained a conversion efficiency matching with that of conventional silicon-based photovoltaic cells.

Wang *et al.* (2003) have synthesized a new ruthenium sensitizer *cis*- $\text{RuLL'}(\text{SCN})_2$ ($L = 4,4'\text{-dicarboxylic acid-2,2'-bipyridine}$, $L' = 4,4'\text{-dinonyl-2,2'-bipyridine}$) in combination with a quasi-solid-state polymer gel electrolyte. Ultra-microelectrode voltammetric measurements indicate that the triiodide/iodide couple can transport charge freely in the polymer gel. The dye sensitized solar cell has unprecedented high stability under both thermal stress and at the time of absorbing light that matches the durability criteria for outdoor applications. The efficiency of the system is above 6% under sunlight. The solar sensitized device showed excellent thermal stability at $\sim 55^\circ\text{C}$ for $\sim 1000\ \text{h}$ in a solar simulator ($100\ \text{mW cm}^{-2}$) that is equipped with a ultraviolet filter. The complex has been synthesized following the **Scheme 2**.

Significant modifications were done by Jang *et al.* (2006) by changing the anchoring group. Implementing the idea, two ruthenium based sensitizer materials have been synthesized i.e., $\text{Ru}((4,4\text{-dicarboxylic acid-2,2'-bipyridine})(4,4'\text{-bis(p-hexyloxy)styryl)-2,2'-bipyridine})(\text{NCS})_2$ and $\text{Ru}((4,4\text{-dicarboxylic acid-2,2'-bipyridine})(4,4'\text{-bis(p-methoxy)styryl)-2,2'-bipyridine})(\text{NCS})_2$, coded as K-19 and K-73, respectively. The compounds were characterized by various sophisticated spectroscopic tools like $^1\text{H-NMR}$, FT-IR, UV-vis absorption, emission spectroscopy, excited-state lifetime and Spectro electrochemical measurements. It has been claimed that these two ruthenium dyes with (K-19) and without amphiphilic chains (K-73) show very striking features with respect to photovoltaic performance and stability. Devices based on the K-73 dye and a nonvolatile electrolyte yielded an unprecedented overall

Scheme 3 Schematic representation of the reaction and the molecular formulas of D5 and D6.

Fig. 5 The structures of Ru-bpy-TPA and Ru-bpy-Me respectively; **Fig. 6** The structures of K9 and K23 respectively.

conversion efficiency of 9% under simulated global air mass 1.5 sunlight at 1000 W/m² intensity. The high extinction coefficients of these sensitizers enables these dyes, a new generation thin film dye sensitized solar cells yielding high conversion efficiency even with viscous electrolytes based on ionic liquids or nonvolatile solvents. The incorporation of the alkoxy styryl group helps in the conjugation of the bipyridine donor ligand increasing profusely their molar extinction coefficient and solar light harvesting ability. Dye sensitized solar cells incorporating the K-19 dye in combination with a binary ionic liquid electrolyte gave over 7.0% efficiency and maintained excellent stability under light at ~ 60°C for ~ 1000 h.

Incorporating electron donating group in the anchoring group, Snaith *et al.* (2008) have synthesized two novel 4- and 4,4'-oligophenylenevinylene-functionalized Ru^{II} bipyridine sensitizers materials coded as D5 and D6. Authors claimed that both of these dyes showed higher photocurrents as well as higher efficiencies for their cells compared to those of cells containing N3 dye [Ru (dcbpyH₂)₂(NCS)₂], herein dcbpyH stands for 4,4'-dicarboxy-2,2'-bipyridine. According to the report, the short circuit photocurrent densities for N3, D5, and D6 are 9.8, 10.8, and 11.7 mA/cm², and the efficiencies are 4.1%, 4.6%, and 4.8%, respectively. Corresponding enhancements in photon to current conversion efficiency values are attributed to the oligophenylenevinylene groups of D5 and D6 that contains conjugated double bonds. The Schematic diagram (Scheme 3) of the reaction and the molecular formulas of the complexes are shown below.

Chen *et al.* (2009) have synthesized two novel bipyridyl-NCS ruthenium complex sensitizers, i.e., Ru-bpy-TPA (TPA = triphenyl amine) with extended π conjugation and Ru-bpy-Me without conjugation system. It has been claimed that by incorporating the TPA unit to the backbone of the dye molecule, the molecular extinction coefficient has been remarkably enhanced resulting in high light harvesting and photocurrent generation. The resulting solar power to electricity conversion efficiency for the solar cell has been phenomenally increased from 2.4% to 3.2% when comparing the new sensitizer of an analogy with no conjugating group. The structures (Fig. 5) are drawn below.

Jang *et al.* (2009) have reported two ruthenium based novel sensitizers i.e., Ru(4,4'-dicarboxyvinyl-2,2'-bipyridine)(4,4'-dinonyl-2,2'-bipyridine)(NCS)₂ (coded as K9) and Ru(4,4'-dicarboxy(phenylethenyl)-2,2'-bipyridine)(4,4'-dinonyl-2,2'-bipyridine)(NCS)₂ (coded as K23). The complexes were characterized by spectroscopic, analytical and electrochemical impedance measurements. Incorporation of the conjugated linkers on the anchoring bipyridyl group that enables enhancements in the short-circuit photocurrents of the thin film DSSCs as compared to conventional Z907 dye (Ru(4,4'-dicarboxy-2,2'-bipyridine)(4,4'-dinonyl-2,2'-bipyridine)(NCS)₂) sensitized cells due to increased molar extinction coefficients and enhanced spectral response in the visible light and the near-IR regions. The conversion efficiencies of K9, K23 and Z907 were 4.14%, 4.41% and 4.06% respectively.

Kisserwan and Ghaddar (2011) have synthesized novel heteroleptic ruthenium complex, coded CYC-B11 (Fig. 6), introducing an electron enriched hexylthio-bithiophene antennas. It has been claimed that this ruthenium complex with the new concept of

Scheme 4 Schematic representation of synthesis of SCZ-1 & SCZ-2.

Recently, Ashraf *et al.* (2017) have synthesized and characterized two unique tris-heteroleptic thiocyanate-free Ru(II) complexes created on bi-imidazole moiety varying the ancillary ligand. The dye with carbazole was coded as SD-15 and with triphenyl amino group was coded as SD-16. Both the sensitizers gave overall power conversion efficiency of 3.3% (Table 2).

Though there are some disadvantages of the Ruthenium complexes such as their higher costs but polypyridine complexes of Ruthenium have intense charge transfer absorption across the whole visible range and have easy tunable redox properties creating them gain superior to other metal sensitizers. Later on, a modified DSSC has been described which is known to be “e DSSC”. This has come into existence because of the encapsulation problem posed by the use of liquid in the conventional wet type DSSC. With the rising research in the different domains of DSSC including sensitizers, semiconductors, thin films, redox couples, the efficiency has already risen from 7% to ~11% leading to the introduction of DSSCs commercially over the conventional silicon based solar cells, which acutely suffers from degradation due to the well-known Staebler-Wronski effect, in the upcoming future.

DSSCs: A Next Generation Power Source With Strategies Towards GHGs Mitigation and Low Carbon Foot Print Through a Renewability Approach

Urbanization of human civilization is over filling the atmosphere with several toxic pollutants which hampers the balance of our ecosystem. In addition, increasing rate of greenhouse gas emission is enhancing global warming index which results in steady drive up the planet's temperature. The present CO₂ foot print in our atmosphere is approximately 410 ppm. One of the major sources of CO₂ emission is electricity in thermal plants, which accounts more than one-third of world's global warming. Indeed, most of the thermal plants are generating electricity by coal-burning and in some cases by utilizing natural gases. In contrast, renewable energy sources can produce very minuscule amount of carbon footprint. According to a survey of energy supply options, the sun is the only fresh energy resource in sufficiently abundant supply to meet global energy demand, though less than 0.1% of our energy

needs are met through the direct conversion of sunlight. To meet up this global energy demand, there are a number of “next generation” technologies on harvesting sunlight with more eco-friendly materials. Dye-sensitized solar cells (DSSCs) and organic solar cells are currently showing high efficiency in terms of their efficiency, thermal stability and commercialization though there remains much fundamental information to be learned within this diverse arena. In this perspective solar energy has achieved a massive footprint in India’s energy basket. It has contributed around 39% i.e., over 7100 megawatts (MW) to the overall total capacity additions (according to data from Mercom Capital Group, a US-based research and consulting firm). In a nutshell, the country has a total solar capacity of around 14.7 gigawatts (GW), (1 GW = 1000 MW) as of September 2017 (see “Relevant Websites section”). According to data aggregated by the International Panel on Climate Change, global warming emissions associated with renewable energy which includes fabrication, installation, commissioning and maintenance, and dismantling and decommissioning are minimal. Increasing the supply of renewable energy would allow us to replace carbon-intensive energy sources and significantly reduce greenhouse gas emissions. In addition to reduced GHG emissions, these technologies can provide other important environmental benefits; in particular non-combustion based options can put forward benefits like elimination of air pollution by low emission of suspended particulate matter as well.

Concluding Remarks

Unprecedented hike in the demand of energy along with the awareness about health and environmental hazards of fossil fuels have made researchers to look into different aspects of Dye sensitized solar cells as the alternative clean and renewable energy sources. In this regard, our emphasis has been given on mitigation of greenhouse gases and carbon foot print through renewability approach. With the beginning of nanotechnology it has become increasingly possible to understand, control and direct the material properties in an exceptional manner as a result of which several new concepts and designs of solar cells devices have emerged. Many sensitizers including both inorganic and organic dyes have been used to fulfill the energy demands of future generations in an environment friendly and sustainable way. Among them, Ruthenium complexes have been preferred owing to the high conversion efficiency which now has reached up to ~ 11%.

Recent developments in the area of DSSCs have lead researchers to invent some dyes which absorb across the visible spectrum leading to higher light to energy conversion efficiencies. Apart from these, cost reduction and simplification of the manufacturing procedures of dye solar cells are also to be emphasized. So that in near future, the DSSC will be the only alternative way to fulfill the energy needs of the planet within next few years.

Introduction

- Growing cooling need as developing world fast approaches the developed economy

Cooling methods and needs have both been evolving over thousands of years. However, the recent and anticipated rise in cooling need has surpassed all previous records probably because the developing world, where about 70% of the world's population resides, has begun to employ large and small scale application of cooling systems in the commercial as well as domestic sector as if repeating a historic trend of the developed world. Pérez-Lombard *et al.* (2008) pointed out that energy consumption of buildings in developed countries comprises 20%–40% of total energy use and is above industry and transport figures in the EU and USA. With the consolidation of the demand for thermal comfort, HVAC systems (and their associated energy consumption) have become an unavoidable asset, accounting for almost half the energy consumed in buildings, and around 10%–20% of total energy consumption in developed countries. The growing trend in building energy consumption, HVAC in particular, will continue even more so with a similar evolution now happening in the developing world that was earlier experienced in developed world, as total energy consumption is increasing in the larger population as a whole. For example, in India, NITI Aayog (2015) estimated that 70% of the buildings in 2030 would be found to be constructed during 2010–2030 only. Studies have shown that India's domestic sector alone calls for a 40% rise in cooling need for urban India and 21% per annum for rural India, calling for 10,386 MW additional capacity in three years (Choudhury and Ray, 2012) and solar operated VACSs, are feasible (Prabhune and Choudhury, 1995), elaborated in this article. Saastamoinen and Paiho (2018) reported that the global cooling demand is expected to increase sharply by 2050 by almost 150% primarily because of population and economic growth, change in lifestyle and energy system development, global warming, as well as quantity and quality of buildings and urban development. Analysis by Sachar *et al.* (2018) shows that at the current growth trajectory of RACs, by the year 2100 the world may see a more than 50-fold increase in the cooling energy demand since the start of the century, solely contributing to over 0.5°C increase in global surface temperatures. The trend in the global context, mentioned below in this article, could well emphasize the need for holistic development of VACS, which has been identified to be the most promising among the solar cooling systems alternative to conventional cooling systems (Al-Zubaydi, 2011) in spite of several barriers to be overcome. Cases from the EU, USA, and India have been presented toward the end of this article to highlight the global trend of RE operated VACS.

- VACS to play an important role for development in the LCE path

The plot of Energy Consumption per capita versus Human Development Index (HDI) for various countries of the world is parabolic in nature, showing a rise of the former with increment of latter (Fig. 1), but at diminishing rate of return (Steinberger, 2016). This observation is corroborated by UNDP (2018) clearly observing that while most countries of the world are showing an increasing trend of HDI (Fig. 2), business-as-usual approaches must change, with countries at different levels of human development exposed to

Fig. 1 Energy Consumption per capita vs. Human Development Index. Reproduced from Steinberger, J.K., 2016. Energising Human Development. Dr. Julia K. Steinberger, Associate Professor in Ecological Economics, Sustainability Research Institute, University of Leeds, United Kingdom. United Nations Development Programme, Human Development Reports, April 14, 2016. Available at: <http://hdr.undp.org/en/content/energising-human-development> (accessed 15.04.19).

Human Development Index values, by country grouping, 1990–2017

Fig. 2 Most countries of the world showing an increasing trend of Human Development Index. Reproduced from UNDP, 2018. Human Development Indices and Indicators 2018. New York: Statistical Update the United Nations Development Programme. Available at: http://hdr.undp.org/sites/default/files/2018_human_development_statistical_update.pdf. (accessed 30.04.19).

and contributing to environmental degradation in different ways, CO₂ emission in particular. Very high human development countries (HDI ≥ 0.8) are the biggest contributors to climate change, with average carbon dioxide emissions per capita of 10.7 t, compared with 0.3 t in low human development countries (HDI < 0.55) as shown in Fig. 3. The considerable variation within the developed nations reveals the opportunity for developing nations to follow a cleaner path of development: Qatar (HDI 0.856) had the highest carbon dioxide emissions per capita in 2014 (> 45 t per person), while Uruguay (HDI 0.804) released only 2 t per person. Further studies within such countries (viz. Qatar versus Uruguay) help to understand the sectorial issues and opportunities for improvement. The energy sector is the largest contributor to carbon dioxide emission where we burn fossil fuel to produce energy. The developing world cannot become developed by following the average path of development, but by assimilation of the lessons learned and applied depending on location, time as well as users' need, taste, and economic conditions. WICEE and GTZ (2004) emphasize the need to make sustainable energy systems integrating EE and renewable energies an important subject for the discussion and implementation on rapidly intensifying international transfer of know-how. In 2018 and 2019, two landmark steps were taken for the first time (International Energy Agency (IEA), 2019a; "see Relevant Websites section"). First, the Cooling Action Plan – the first of its kind in the world – that has put forth multiple proposed interventions to address cooling across multiple sectors in India, and second, the "First-ever global coalition for clean cooling" by the United Nations. Thus, rapid rise of HVAC calls for urgent action toward LCE in favor of development of VACS driven by renewable energy. also discussed in this article.

- Potential of RE can be fully realized through adaptation of environmentally benign technologies such as VACS

The sun is a smaller star among several hundred billion stars in our Milky Way alone. Earth receives only a tiny fraction (less than a billionth) of energy released from the sun in all directions, yet that is several thousand times more than what even modern human civilization consumes today, which includes the old stock (of solar energy) now explored as fossil fuels, viz. coal, oil, and gas, along with the present forms of renewables, viz. solar and its derivatives, such as wind, biomass, ocean thermal, etc. The energy sources that also play a significant role albeit out of this energy chain, viz. nuclear fission, geothermal, and tidal, having no direct emission of CO₂ in the energy conversion process, are also sometimes termed as renewable though this is debatable. Since the Industrial Revolution, our economy has become too carbonized through rampant consumption of fossil fuels. Decarbonization of the economy is crucial for the survival of modern civilization and calls for judicious use of energy resources through EE and application of RE in all possible ways. Active systems utilize RE directly, such as solar water heaters, renewable energy driven VACSs, etc. Huge potential of REs can further be explored by employing passive systems as well, such as passive architecture in buildings, natural cooling, etc. For example, through passive architecture, the cooling load of a building has been reported to be reduced by 25% (Radhi, 2009). Such initiative can also reduce the size of required active

Carbon dioxide emissions per capita, by human development group, 2014 (tonnes)

Fig. 3 Carbon dioxide emissions per capita, by human development group, 2014 (t). Reproduced from UNDP, 2018. Human Development Indices and Indicators 2018. New York: Statistical Update the United Nations Development Programme. Available at: http://hdr.undp.org/sites/default/files/2018_human_development_statistical_update.pdf. (accessed 30.04.19).

cooling systems and make the overall economy favorable that can be revealed through application of tools, viz. life cycle cost analysis by Beccali (2010) for solar cooling systems of IEA SHC Task 38 Solar Air Conditioning and Refrigeration, where solar thermal collectors' inclusion caused a reduction of net benefits of about 15%, with a payback time of about 3 years.

Several countries in the world have been successfully implementing 100% RE initiatives. These are already a reality in more than 180 sites around the globe (Kumar *et al.*, 2018). The Sierra Club's 2016 report showcases 10 U.S. cities that have made ambitious commitments to be powered by 100% clean (renewable) energy, that will help save taxpayer dollars, help their residents save money, create good jobs, and foster a better quality of life, in the backdrop that solar and wind energy prices have dropped 80% and 60%, respectively, in recent years. Georgetown, Texas, found that renewables made sound fiscal sense as it could lock in lower rates for solar power, and renewables use far less water than fossil fuels – critical in a state accustomed to drought. Clean energy can bring economic benefits to every American family. Studies by Stanford scientists revealed that the transition to a clean energy economy would save the average American family over \$200 a year in energy costs and \$1500 a year in healthcare costs as clean energy cuts pollution and saves lives. According to a national survey conducted by the University of Texas at Austin in spring of 2016, 90% of American adults agree that the government should be focusing on developing renewable energy. The report also mentioned that Burlington, Vermont; Aspen, Colorado; Columbia, Maryland; and Greensburg, Kansas, had already achieved 100% clean energy, powering their cities entirely with renewable sources, and proclaimed further that a dozen additional cities have made commitments to reach 100% clean energy in the next 15–20 years, and many others were considering similar plans. Sukumaran and Sudhakar (2017) reported the case study of fully solar powered Cochin International airport operating at 87% performance ratio and 20% capacity utilization factor.

The Kigali Amendment to the Montreal Protocol on hydrofluorocarbons, which cause ozone layer depletion, and the subsequent K-CEP launched in 2017 are working closely with partners across multiple countries to promote major EE gains and sustainable cooling solutions, bringing together philanthropic foundations, technical experts, international organizations, and other cooling partners, unleashing the huge potential for faster applications of solutions, such as VACS driven by renewables.

- VACS driven by renewable energy for CO₂ emission reduction toward achieving Sustainable Development Goal (SDG) 7

Among 17 goals set by the United Nations General Assembly in 2015, SDG 7 targets to “ensure access to affordable, reliable, sustainable and modern energy for all” within the year 2030. In support of these efforts, the IEA, the lead custodian agency for SDG 7.2 on renewable energy and 7.3 on EE, developed the SDS in World Energy Outlook 2017. The SDS combines ambitious climate policy (SDG 13) with significant action on achieving energy access (SDG 7.1) and creating cleaner air (SDG 3) – An integrated approach that speaks to energy policy priorities in a very wide range of countries (International Energy Agency (IEA), 2018a). Energy demand for cooling is the fastest growing end-use in buildings. Sales are rising three times faster than efficiency improvements, and more than 10 air conditioners will be sold every second over the next 30 years. Meanwhile, carbon dioxide

(CO₂) emissions from cooling have tripled since 1990 to 1130 million tons (Mt), equivalent to the total emissions of Japan (International Energy Agency (IEA), 2018b). To put cooling on track to meet the SDS target, minimum energy performance standards need to push markets to improve AC performance by more than 50% by 2030. This could cut CO₂ emissions from space cooling in half while reducing local air pollution. The IEA also launched in 2018 the Kigali tracker under its Global Exchange Platform to work with countries and K-CEP partners to track information on EE, refrigerants, investments, and policies. If improvements in the EE of cooling equipment continue to lag behind increases in sales, air-conditioning electricity demand could increase by as much as 60% globally by 2030 – 40% greater than the pace needed to match SDS targets.

This cannot be achieved without attaining EE and switching over to alternative sources such as renewable energy in particular. While launching the Cool Coalition, the United Nations revealed that emissions for cooling sector are set to increase 90% by 2050 if no action is taken. The energy sector happens to be the largest contributor to global CO₂ emission and buildings in EU and USA consume more energy than other sector sectors of economy, viz. transportation and industry. Therefore, to ensure sustainable modern energy for all, both EE and renewable energy use are essential and important. Thus, renewable energy driven VACS, elaborated in this article, are among few that meet both needs. Fahléna *et al.* (2012) pointed out that absorption cooling has potential for cost-effective CO₂ reduction.

Principle of Operation of Vapor Absorption Cooling System

Reversed Heat Engine Cycle for Vapor Absorption Cooling

In a heat engine cycle, flow of heat from a high temperature source to a low temperature sink is utilized to run a working fluid, say, water, through boiler–turbine–condenser–pump–(back to) boiler cycle, as the turbine drives an alternator to produce electricity, essentially from heat produced by combustion of a fuel, say, coal or oil or gas. In a reversed heat engine cycle [popularly known as VCCS, comprising evaporator–compressor–condenser–throttle–(back to) evaporator], heat flow apparently takes place from a low temperature source (sink, in previous case) to a high temperature sink (source, in previous case). Thus, the system is driven by a compressor raising the pressure of working fluid [popularly known as refrigerant, such as ammonia (NH₃), hydrofluorocarbon (HFC), chlorofluorocarbon (CFC), etc.] in gaseous form, that is, large specific volume and hence by consumption of significant amount of electricity to run the compressor, as $p dV$ work will be high. That is the reason why the EER is sought to be higher while selecting such systems with huge running cost of energy consumption, compared with a lower cost of initial investment for the purchase of the system.

Whereas, in vapor absorption cooling, as shown in Fig. 4, the compressor is replaced by another cyclic system of absorber–pump–generator–throttle–(back to) absorber, drastically reducing the need for electricity as pump handling liquid with much lower specific volume has much less $p dV$ work for similar pressure rise and mass flow rate. However, the additional system component, the generator (also known as desorber), would need some heat input, which is made available from the existing system, and could be low pressure steam or hot water generated from locally available renewable energy sources or waste heat. The vapor absorption systems have experienced a comeback nowa days as the savings due to lower electricity consumption outweigh the incremental cost for larger initial investment plus the cost of heat required at the generator. Among a large number of pairs available, techno-commercially most common working pairs are H₂O–LiBr and NH₃–H₂O nowadays (Saastamoinen and Paiho, 2018; Choudhury, 2019); both are non-CFC gases and not listed among the six GHGs as per the Kyoto Protocol. Solar energy driven NH₃–H₂O systems' performances are reported by Brice Le Lostec (2012) and Jawahar and Saravanan (2013). Jawahar and Saravanan have done an experimental study on the ammonia water VACS using a high-pressure and a low-pressure generator–absorber–heat exchanger system and the COP was found to be 0.61. Brice Le Lostec (2012) has done an experimental study on an ammonia water absorption chiller cooled with water–ethylene glycol solution. The required heat source is hot water ranging from 75–85°C and the COP was found out to be 0.6. A theoretical analysis on H₂O–LiBr and NH₃–H₂O VACSs can be obtained at IIT Kharagpur (2014, 2015, 2017).

Gomri (2013) has done a simulation study on the performance of a solar/natural gas operated H₂O–LiBr VACS and shown that the CO₂ emission is reduced by a considerable amount when compared with VCCS. Saleh and Mosa (2014) has done an optimization study on a single effect H₂O–LiBr absorption system powered by flat plate solar collectors and the COP was found to be 0.82. The generator temperature was 80–90°C and so the H₂O–LiBr system was found to be more suitable for solar applications. The present study further reviews several opportunities for improvement of efficiency and performance of renewable energy operated VACS including proposal of an innovative application of double acting reciprocating pumps as power exchanger to further reduce the power consumption thereby increasing the COP and enhancing opportunity for such system to be driven by renewable energy systems – solar energy in particular.

Coefficient of Performance of Cooling Systems

COP of cooling systems may be defined as the ratio of desired output, that is, the cooling effect to necessary input, that is, the power and heat (if any) input to be provided to run the system. COP varies from 2.30 to 3.10 for conventional cooling systems, that is, those running on VCCS. If the electrical input is corrected for its thermal use of primary energy resources, these values assume the range from 0.70 to 1. On the other hand, VACS use only a tenth to seventh part of electricity being used by its VCCS counterpart – the same being compensated by low temperature thermal energy input to its 'generator', and has typical COP of

Fig. 4 Schematic diagram of single stage lithium bromide–water vapor absorption cooling system. Reproduced from Florides, G.A., Kalogirou, S.A., Tassou, S.A., Wrobel, L.C., 2003. Design and construction of a LiBr–water absorption machine. *Energy Conversion and Management* 44 (15), 2483–2508. Available at: https://s3.amazonaws.com/academia.edu.documents/47750868/s0196-8904_2803_2900006-220160803-26866-n7qel5.pdf?AWSAccessKeyId=AKIAIWOWYYGZ2Y53UL3A&Expires=1558277831&Signature=Oph6t1klS5Kt%2FYYPxw5ZHfOccE%3D&response-content-disposition=inline%3B%20filename%3DDesign_and_construction_of_a_LiBr_water.pdf.

0.704–0.95 If this COP is corrected to calculate in the same way as was done for VCCSs, it would be found to vary from 2.1 to 2.7. Many such VACS run on waste heat to meet the thermal energy input.

Cooling Systems' Performance Measured in the Market

In the market, cooling systems are generally measured in terms of EER, SEER, and CEC and expressed as follows:

COP is cooling produced per unit of heat or electricity used, $W(W)^{-1}$, a nondimensional quantity, calculated as EER divided by 3.412.

EER is cooling produced per unit of heat or electricity used, Btu per h/Input W, calculated as COP multiplied by 3.412, as $1 \text{ kW} = 3412 \text{ Btu per h}$. However, if EER is expressed as kJ cooling per hour $(W)^{-1}$, $\text{COP} = \text{EER}/3.6$.

The theoretical efficiency limit is the efficiency of a Carnot cycle operating between two temperatures. Considering a typical outside temperature of 35°C and inside temperature of 27°C , the maximum possible efficiency (COP in case of these cycles operating in reversed heat-engine mode) is 37.5 W/W . The best available room air conditioners in the world have a COP of around six or EER 21.6. This calculation for a Carnot cycle is based on the sensible cooling load only (i.e., cooling the air from a source temperature of 35°C to a sink temperature of 27°C) and ignores the latent load impact. In addition, Sachar (2018) observes that latent load, if any, can be met via a desiccant system with 100% theoretical efficiency. This is further in accordance with the BEE, Government of India, standard test conditions for evaluating the cooling capacity of variable capacity room air conditioners in India, where the expression of EER and COP are just interchanged.

SEER is seasonal EER, calculated by dividing total cooling produced in an annual cooling season to the total heat or electricity input to the system during the same period. Thus, if EER is a functional parameter, SEER is an operational parameter. SEER aims to increase the efficiency of ACs, helping consumers get lower bills even in higher temperatures. A SEER rating of 14–22 is considered to be good.

CEC is calculated to determine the star rating band and star rating of the model of a cooling system employing a correlation involving cardinal parameters as applicable, such as total adjusted storage volume for a household frost-free refrigerator.

Concept of Levelized Coefficient of Performance

$$\text{COP of a refrigeration system is} = \frac{\text{Cooling Effect (CE)}}{\text{Input Driving Energy (IDE)}} \quad (1)$$

In case of VCCS (electrically driven)

$$(\text{COP})_{\text{VCCS}} = \frac{\text{CE}}{\text{IDE}(\text{Electrical})} \quad (2)$$

In case of VACS (thermally driven)

$$(\text{COP})_{\text{VACS}} = \frac{\text{CE}}{\text{IDE}(\text{Heat}) + \text{Electricity}(\text{one} - \text{seventh part of normal VCCSs})} \quad (3)$$

Levelized COP is also termed as PEE (taking into consideration the fact that heat is a lower grade energy than electricity with a conversion factor of about 33.9% (Ministry of Power, Government of India, 2015).

$$(\text{COP})_{\text{Levelised VACS}} = \frac{\text{CE}}{\text{IDE}(\text{Heat}) \times (33.9/100)} \quad (4)$$

$$= \frac{2.94 \times \text{CE}}{\text{IDE}(\text{Heat})} \quad (5)$$

$$= 2.94 \times (\text{COP})_{\text{VCCS}} \quad (6)$$

Thus, COP of VACS may be compared with the COP of conventional vapor compression system only after normalizing it as mentioned above, that is, multiplying by 2.94 if they were levelized by making them comparable on a similar plane. Here IDE (Electrical $\times 0.339 / 7$) has been considered to be negligible as applied in the system shown in Fig. 4. Typical values for a single stage (Florides *et al.*, 2003) shown in Table 1 will give an idea why LiBr–H₂O VACSs are often selected for being driven by solar thermal energy (Q_g) input to the generator (at 90°C) for space cooling applications (cooling effect provided at 6°C or above).

Vapor Absorption Cooling System Driven by Renewable Energy

Abu-Zour and Riffat (2007) made a review of the then existing VACS and classified solar driven systems and Al-Zubaydi (2011) showed that VACS is more promising for solar thermal application. However, today, a large number of options are available and more are evolving for efficient use of various renewable energy sources for cooling purposes, as shown in Fig. 5, indicating nonsingularity of the solution, rather keeping the option open for optimization.

VACS driven by RE refers to the systems that procure the necessary thermal energy for heating of generator from one or more renewable energy sources. However, such systems, in addition to thermal energy, may also utilize renewable energy source to meet the (meager or much less than their VCCS counterpart) electrical energy to run the pump. VACS can be driven by various renewable energy sources, as follows:

- (1) Solar thermal energy: SWHSs or SSGSs or solar air heaters can drive any of the five types of the solar thermal cooling systems, viz. absorption, adsorption, ejector systems, desiccant cooling, thermomechanical. Even SFPC are utilized to provide

Table 1 Cardinal parameters for single stage vapor absorption cooling system

Point	Enthalpy (kJ/kg)	Mass flow rates (kg/s)	Pressure (kPa g)	T (°C)	Remarks
1	83.0	0.0530	0.934	34.9	Normal temp low pressure rich solution
2	83.0	0.0530	9.660	34.9	Normal temp high pressure rich solution
3	145.4	0.0530	9.660	65.0	Subcooled liquid
4	212.2	0.0486	9.660	90.0	Warm high pressure lean solution
5	144.2	0.0486	9.660	54.8	Normal temp high press lean solution
6	144.2	0.0486	0.934	44.5	Normal temp low pressure lean solution
7	2628.0	0.0044	9.660	85.0	High pressure superheated steam
8	185.3	0.0044	9.660	44.3	High pressure saturated liquid water
9	185.3	0.0044	0.934	6.0	Low pressure warm refrigerant liquid
10	2511.8	0.0043	0.934	6.0	Saturated vapor
11	23.5	0.0001	0.934	6.0	Saturated liquid water

Note: Florides, G.A., Kalogirou, S.A., Tassou, S.A., Wrobel, L.C., 2003. Design and construction of a LiBr–water absorption machine. *Energy Conversion and Management* 44 (15), 2483–2508. Available at: https://s3.amazonaws.com/academia.edu.documents/47750868/s0196-8904_2803_2900006-220160803-26866-n7qel5.pdf?AWSAccessKeyId=AKIAIWOWYYGZ2Y53UL3A&Expires=1558277831&Signature=Oph6t1kl5SKt%2FYYPXw5ZHfOccE%3D&response-content-disposition=inline%3B%20filename%3DDesign_and_construction_of_a_LiBr_water.pdf.

Fig. 5 Classification of cooling systems driven by renewable energy.

necessary heat (Q_g in Figs. 4 and 5) to the generator to meet the cooling load during summer leading to improved utilizability of SFPC, which normally remains underloaded during summer as size is designed on the basis of critical load, which is in winter. A mathematical modeling by Bajpai (2012) revealed that typically such $\text{NH}_3\text{--H}_2\text{O}$ system of 1 TR capacity would require 24 m^2 SFPC, which would make the system costly but technically feasible for even domestic application. Saha *et al.* (2001) found silica gel–water, when taken as the adsorbent refrigerant pair to exploit solar/waste heat of temperatures below 70°C , COP of only 0.36 could be achieved even at two stage chiller.

- (2) Biomass energy: If a sustainable supply of biomass is available at reasonable price, the same may be utilized or burned to produce heat to be transferred to the generator (Q_g in Figs. 4 and 5). For controlled and clean combustion, biogasification may be employed to produce producer gas.
- (3) SPVS: After thermal energy need at the generator has been met by renewable energy sources, electricity produced by SPVS can be utilized to run the pump, as the requirement of electricity is much lower with compared with the requirement to run the compressor in VCCS. In some cases, solar electricity operated VCCS may turn out to be more beneficial than solar thermal energy operated VACS.

- (4) Wind Energy Generator (WEG): Where available at cheaper rate, power from WEGs could be utilized instead of SPVSs in the above cases.
- (5) Hydropower: Similarly, as above, hydroelectricity could be a favored renewable energy source for driving the pump.
- (6) Geothermal: Geothermal power plants can provide bleed steam from LPTs to meet thermal energy need in the generator and electricity to drive the pump of VACS and also the electricity from geothermal power plants could be a favorable option to run a VCCS or any other system mentioned in Fig. 5.

Opportunities and Barriers for Development of Such Systems

A growing rate (15%) of electricity consumption in buildings goes to heating, ventilating, and air conditioning (HVAC). For some CDDs and HDDs, cooling would be costlier than heating. Buildings account for nearly 40% of global energy consumption. About 40% and 15% of that are consumed, respectively, by HVAC and lighting (Sun *et al.*, 2013). Solar cooling has been found to be a good example of addressing climate change and improving efficiency of solar thermally operated cooling technologies is an essential research need of the hour as well as the future (Al-Alilia *et al.*, 2014).

In developing countries, the building sector has a higher growth rate; for example, the highest is in case of India (Sachar *et al.*, 2018), where according to estimates by NITI Aayog (2015), 70% of the building stock in the year 2030 will be built during 2010–2030. Often, there is a match among the needs, as follows:

- (1) Cooling load generally increases directly with solar radiation, that is, availability of solar energy increases when cooling load is greater.
- (2) SWHS are typically designed for winter load, and therefore, remain largely underutilized during summer, when the hot water need will be much lower than that of the need in winter. Since the system size cannot be changed seasonally, SWHS becomes oversized and much of the capital investment is thus blocked. However, the cooling need is greater in summer. VACS are ideal applications to meet such load utilizing the surplus heat from SWHS employing VACS.
- (3) In the developing world, more buildings are upcoming that would be suitable for directly implementing more energy efficient and effective policy, which includes giving higher priority to VACS, thus avoiding the repetition of the mistakes learned previously.
- (4) In the developed world, opportunities of integration with existing systems, such as DHS, SWHS, etc. could be found to be technoeconomically viable as the utilizability of the existing systems would be enhanced.

In spite of increasing importance, the above-mentioned opportunities would be productive through identification of barriers and analysis to overcome the same as explored in the following section.

Overcoming the Barriers: Technology, Economics, Financial, and Social

Overcoming Technology Barriers

Innovation in technology to overcome barriers

International Energy Agency (IEA) (2019a) begun in 2019 the first ever Technology Collaboration Programmes (TCPs) for Heat Pumping Technologies (HPT TCP) and Energy Storage through Energy Conservation (ECES TCP) to seek to develop a prototype 'Climate Comfort Box' for sharing and dissemination of innovations and applications in this one of the fastest growing area for high efficiencies with flexible storage at affordable prices to deliver on ambitions for affordable heating and cooling. This new Innovation Tracking Framework identifies key long-term "technology innovation gaps" across the energy mix that need to be filled to meet long-term clean energy transition goals. The objective is to highlight where R&D investment and other efforts need improvement. The following are a few such innovative solutions.

Employing double acting pump to operate in power exchanger mode

As cooling demand will continue to grow, innovative technologies may be incorporated as quickly as possible. One of the technological innovative approaches would be application of a power exchanger (PEx), as briefly described below:

Working and Employing of Double Acting Pump in Power Exchanger mode

The innovative application of a double acting reciprocating pump, as proposed in the present study, to act as PEx, would further reduce the electricity consumption by nearly 75% and life cycle cost by nearly 10% especially for WHR VACSs. Here the pressure of the high pressure solution coming from the generator is utilized to pump the weak solution from the absorber to the generator. This reduces the pumping power significantly. When the valves V3 and V4 are closed then the piston moves upward forcing the valves V1 and V2 to open leading the inlet of fluid from the absorber and outlet of fluid to the generator.

When the piston moves upward, valves V2 and V3 are open but the valves V1 and V4 get closed, thus the strong solution from the generator gets stored from the lower chamber of the pump (below piston as shown in Fig. 6). In the same stroke the weak solution in the upper chamber (above piston) in the pump that was stored from the absorber in the previous stroke (piston moves downward) is pumped to the generator.

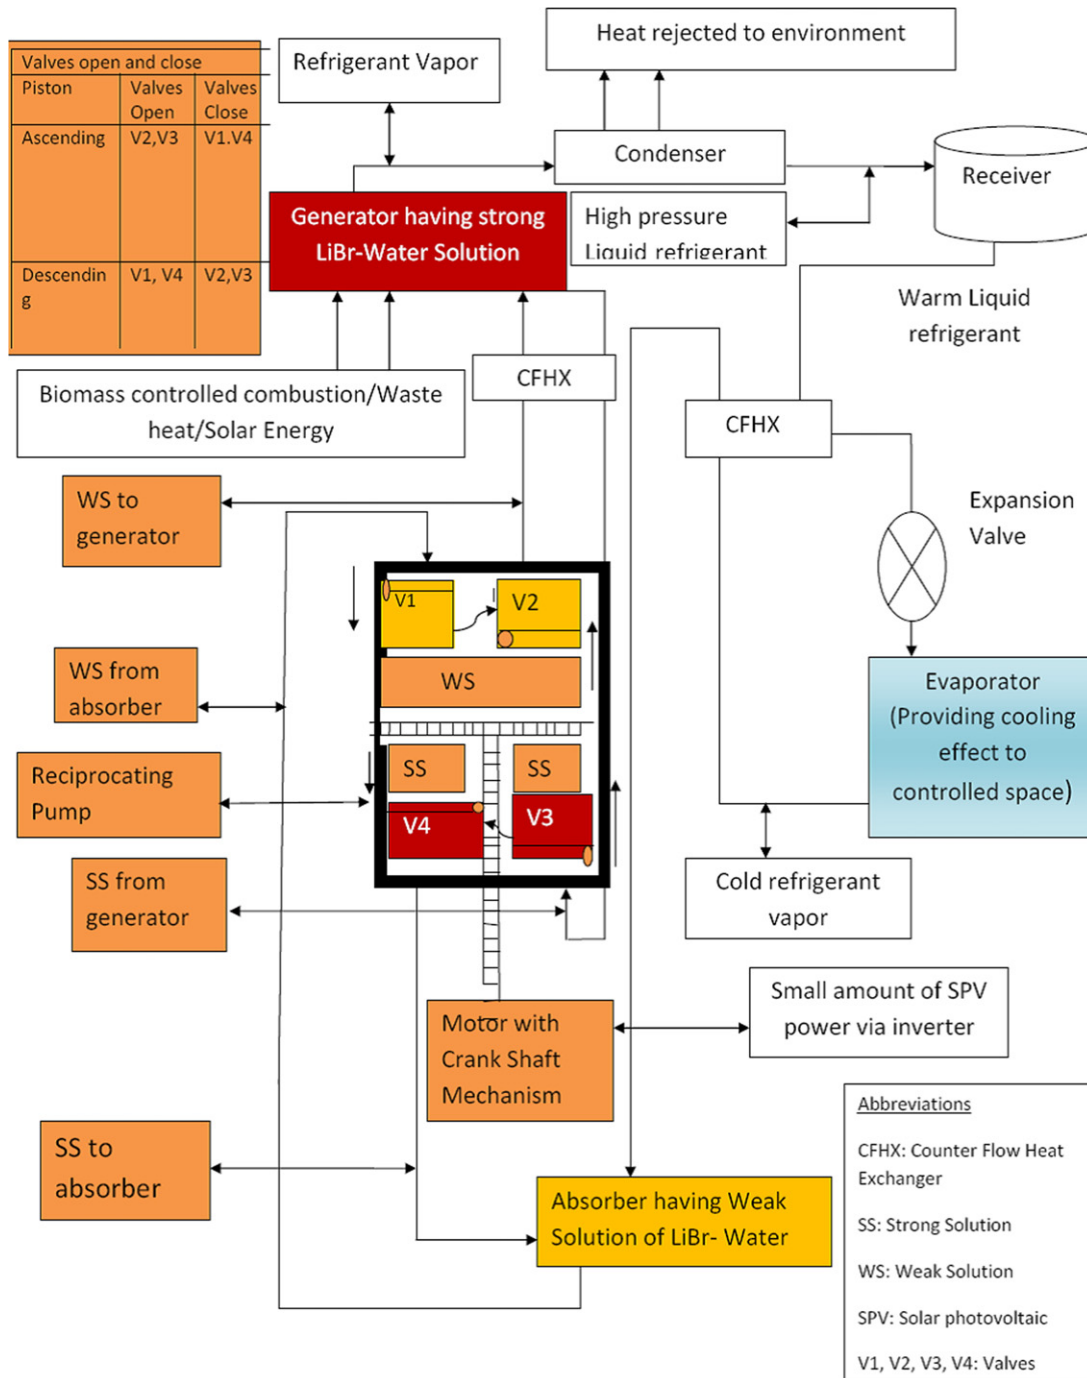

Fig. 6 Schematic diagram of a vapor absorption cooling system (lithium bromide + water) using reciprocating pump (in power exchanger mode).

Similarly when the piston moves downward valves V1 and V4 are open and V2 and V3 are closed. Thus the weak solution from the absorber gets stored in the upper chamber (above piston) in the pump and the strong solution, which was stored from the generator in the previous stroke (piston moves upward), is now pumped into the absorber completing the cycle.

The loss of power due to flow of strong solution from the generator at higher pressure to the absorber at lower pressure is almost recovered with the employment of this double effect reciprocating pump compared with single effect (ordinary) reciprocating pump necessary to transfer the rich solution in low pressure absorber to the high pressure generator. That is why the proposed system is termed as PEx in parity with the working principle and nomenclature of the heat exchanger. Thus by using the reciprocating pump in PEx mode the COP can be increased and the running cost can be lowered as the pump power to the generator is decreased, compared with conventional VACS, and thus makes it more competitive with VCCS.

Fig. 7 Principle of operations of double effect absorption refrigeration system and absorption-compression hybrid refrigeration system recovering condensation heat for regeneration systems. *Source:* Wang, J., Li, X., Wang, B., *et al.*, 2017. Performance comparison between an absorption-compression hybrid refrigeration system and a double-effect absorption refrigeration system. *Procedia Engineering* 205, 241–247. Available at: https://www.researchgate.net/publication/320761741_Performance_Comparison_between_an_Absorption-compression_Hybrid_Refrigeration_System_and_a_Double-effect_Absorption_Refrigeration_System.

Employing double effect absorption refrigeration system and absorption-compression hybrid refrigeration system recovering condensation heat for regeneration for more efficient use of renewable power in cooling systems

Wang *et al.* (2017) have shown through simulation the opportunities for improvement of performance in absorption compression hybrid refrigeration system (RCHG-ARS) by 29% with compared with even a DEARS shown in Fig. 7.

Vapor compression cooling system and vapor absorption cooling system hybrid

The heat of condensation rejected by VCCS if integrated and utilized in the generator of VACS, the combined performance of the system run on renewable electricity could be better (than a single VACS, of capacity same that of the proposed combined system, also run on renewable electricity) in larger applications particularly where such electricity generation and cooling need are directly proportional. This would also help stability in the grid and overcome challenges of large-scale grid integration.

Choosing the correct vapor absorption cooling system technology, alone or hybrid

VACSs can be of various types and selection can be made, depending on combinations of various renewable energy resources with suitable VACS technologies, viz. standard, open cycle, turbo-absorption (Trivichachai and Wongwises, 2003), VCCS-VACS hybrid, etc. with appropriate absorbent-absorber solvent pair considering availability of supplier, maintenance, techno-economic viability, etc. Sreeshankar *et al.* (2014) pointed out that the exhaust gas of vehicles when utilized to run a Seebeck cycle for electricity generation and remaining heat for thermal input to VACSs provides all energy to cool automobile space and cold-storage on heavy vehicles.

Heating from cooling

Just like the old technology of VACS is coming back to meet the modern needs, some of our old concepts may be rethought to fetch huge benefits through replicated applications. Instead of using a separate heating system for any chilled substance to bring to normalcy for consumption/use, if the heat of condensation of the refrigerants is appropriately used, it would not only save energy of separate heating system, but also improve COP of the cooling system.

Fig. 8 Monthly variation of heating, differential heating and cooling degree-days in Helsinki, Finland. *Source:* RETScreen. Available at: <https://www.nrcan.gc.ca/energy>.

Fig. 9 Monthly variation of heating, differential heating and cooling degree-days in Buffalo, USA. *Source:* RETScreen. Available at: <https://www.nrcan.gc.ca/energy>.

Cooling from heating

VACS are essentially such devices that are being optimally operated to utilize the waste/surplus/unutilized/cheaper/less carbon intensive heat available at/near the point where cooling is required. Studies revealed newer ways and means for taking the fuller advantage of VACS. One such example is DHS, which are normally run on CHP mode. RETScreen data reveals that the HDD and CDD have opposite trends. DHS designed on the basis of HDD would be sized considering the maximum value, that is, in peak winter months. In other months, DHS will remain underutilized and hence away from highest efficiency point in proportion to the differential (maximum HDD – current month's HDD), which shows near perfect variation with CDD as shown in **Figs. 8** and **9** for two locations, viz. Helsinki, Finland and Buffalo, USA.

Also, the solar radiation is available more with cooling DD for most places, including Stockholm, Sweden and Canberra, Australia, as shown in **Figs. 10** and **11**. It is interesting to note that Canberra, being located in the southern hemisphere, has a different pattern of solar radiation (when it is winter in the northern hemisphere, summer prevails in the southern hemisphere, and vice versa) but the availability of solar radiation is again more for months with higher cooling DDs. Thus, opportunity for VACS driven by RE is again more. This is corroborated by the observations of *Ilic (2014)* on the monthly variation of heating load in Sweden as shown in **Fig. 12**.

Potential for drastic improvement of performance levels

Carrier launched in 2018 an air-conditioning unit with a SEER of 12.3, three times the market average efficiency of residential air-conditioning unit sales in the United States in 2017. Such initiatives illustrate the potential for cooling equipment to drastically improve performance levels and also calls for innovative action plans to help dissemination of such innovations. Average efficiencies of new air-conditioning units sold would need to move from a SEER of around 4 today to 7 or higher in 2030 – a task that is not insurmountable but one that would require strong market signals and greater collaboration between countries (*International Energy Agency (IEA), 2019a*).

Available at: <http://liu.diva-portal.org/smash/get/diva2:719334/FULLTEXT01.pdf> (accessed 29.04.19).

International Energy Agency (IEA) (2019a,b) also launched in 2018 the Kigali tracker under its Global Exchange Platform to work with countries and K-CEP partners to track information on EE, refrigerants, investments, and policies.

Continual innovations is the solution

Various types of renewable energy driven VACS discussed here are still evolving with improvement of performance in the process of gaining more applicability according to the local conditions, as has been reported by various researchers, showing continual development as one key to overcome the barriers. For example, Al-Zubaydi (2011) refers to one type of recently developed small capacity machine capable of operating at partial load with cooling load with a temperature of 65°C and with an estimated COP of around 0.7, a compromise ideal for solar applications. In another study, one of the simulation results showed the possibility of use of the dry type cooling tower in a solar assisted air condition absorption system with hot water driven ammonia/water absorption chillers in case of lack of fresh water, for example, in a high ambient location in Abu Dhabi (UAE).

Overcoming Economic and Financial Barriers

Higher initial investment plays a negative role on economics of VACSs and one of the reasons for its popularity far behind VCCSs today. However, a good number of conditions in its favor have already been identified as follows:

- The refrigerants used are pairs of solvents and solutes in VACSs and there are more than 50 such pairs are possible. Most common pairs in use nowadays are H_2O –LiBr and NH_3 – H_2O – the former for space cooling at more than 5°C and the latter for refrigeration to lower than 5°C, both being non-CFC gases and not listed among the six GHGs as per the Kyoto Protocol. It may be noted that VCCS were developed to operate with CFCs and other GHGs as refrigerants that were the cause of the ozone hole and global warming, which led to ban of their use in most of the world, which had to spent huge amount to tackle the menace. The indirect benefit to society is therefore quite significant and needs to be quantified and reflected in costing to customers.
- The main driving energy being thermal, waste heat available in industrial installations and in larger buildings (diesel or gas exhaust after combustion in generator-sets or such facilities) is not only free but also may help avoid the cost of treatment of waste heat because of prevailing environmental regulations.
- Moreover, wherever larger installations of solar air/water heating systems or DHS exist, invariably it is observed that during summer such systems are underloaded or nonfunctional. Employment of VACSs utilizing the heating capacity of such systems during summer, when the cooling load is significant, would not only ensure a free source of heat, but also, may improve the performance and/or life of such existing systems.
- Since VACSs driven by renewable energy would help avoid the CO_2 emission that would have happened otherwise with cooling systems run on energy from fossil fuels, the emission mitigation needs to be quantified and reflected in costing to customers. Such mechanism exists in some countries asking polluters to pay the social cost.
- While considering available options of cooling systems, often the decision makers are confused with cost to multiple benefits of the alternatives. Multicriteria decision making (MCDM) processes help the investors to choose among alternatives with different pay-back period, return on investment, internal rate of return, initial investment, CO_2 mitigation, energy saving, working life, resale value, etc. (Majumdar and Choudhury, 2017). While taking into consideration criteria for greening of existing buildings also, retrofitting with VACSs climbs up the ladder to assume top priority in the decision making process (Majumdar and Choudhury, 2018).

Overcoming Social Barriers

Social barriers often assume subtle issues in a complex situation involving economic, cultural, political, climatic, and other aspects of a society. Delicate care is required in designing and planning for awareness programs and relevant policies to overcome social barriers. For example, the “top runner” approach in Japan and standardization and labeling have been a huge success in many countries including India. Japan’s Top Runner Program led to an efficiency increase of 100% from 1995 to 2005, while prices dropped over 80% (Sachar *et al.*, 2018). Availability of decision making tools also will play a positive role. With innovations in improvement of performance, reduction of cost, and productive use of locally available resources to meet the need would encourage more people to explore the huge benefits of VACSs taking it to a favorable cycle (more positive initiatives – lower cost at improved performance – more use – realization of benefits – more popularity – more production – more positive initiatives) from a vicious cycle.

NZEBs are expected to play an important role in fighting climate change and reducing the energy use of the built environment (Robert and Kummert, 2012). Baniyounesa *et al.* (2014) points to commercial buildings with large roof areas, such as supermarkets, shopping centers, hotels, hospitals, and convention centers, as most suitable for VACS by solar systems and emphasize on a set of rules that should be undertaken by operators, supervisors, and project managerial teams to ensure occupational health and safety guidelines, site preparation, site security, environmental considerations, and identification of general hazards and their control. Major challenges faced by cities in moving to 100% renewable energy, with need for cooling in place, identified in the dialog held in conjunction with COP 21 at Paris in 2015 (Jacquet *et al.*, 2015), were in order of number of responses (high to low) per thematic challenge: (1) Lack of jurisdictional control, (2) lack of political will at the national level, (3) limited access to sufficient RE resources, (4) transitioning from cheap coal, (5) vested interests in fossil fuels or nuclear, (6) building retrofits and housing, (7) fleet conversion, (8) transportation, (9) transitioning industry from fossil fuels, (10) scaling up RE with limited financial resources, and (11) public support, as shown in Fig. 13.

Fig. 13 Major challenges faced by cities in moving to 100% renewable energy. Reproduced from Jacquet, E., Small, M., Marques, A., Leidreiter, A., 2015. Dialogue report: 100% Renewable energy in cities. TAP 2015 – COP21. Le Bourget, Paris. Retrieved from May 11, 2019. Available at: <https://www.renewablecities.ca/rc/wp/wp-content/uploads/North-American-Dialogue-Report-Print.pdf>.

Role of Tools to Overcome Barriers

Standard tools and techniques are available to evaluate existing and proposed systems. Energy audits can evaluate the energy performance of VACSs as well and point out the opportunities for improvement. A number of simulation software programs give the opportunity to assess the performance even at the design stage. With the employment of such tools, cost-benefit and other economic analysis can be faster, unambiguous, and versatile. Postoccupancy evaluation of actual building energy consumption, say in VACSs, is being compared with the design values, and taking users into confidence, significant energy savings have been achieved through improved maintenance, temperature set points, and control.

Ranking among alternative cooling systems with various combinations, viz. high cost – high efficiency, high cost – low efficiency, low cost – high efficiency and low cost – low efficiency, is also possible through such tools and techniques helping the decision making process. Social awareness can be raised significantly by showing various scenarios simulated by such tools (Majumdar and Choudhury, 2017). Many software tools are used to generate and assess alternative scenarios, simulate, and/or assess project alternatives and system performances (technological, financial and social), viz. EnergyPlus, eQUEST, MATLAB, PVSyst, RETScreen, SolarGis, TRNSYS, etc.

Many of the studies reported in this article (Al-Zubaydi, 2011; Fahléna *et al.*, 2012; Gomri, 2013; Robert and Kummert, 2012; Sukumaran and Sudhakar, 2017; Sun *et al.*, 2013) give interesting and conclusive outputs through application of simulation techniques. Peters (2018) emphasizes application of simulation tools and identified six recommendations to overcome barriers:

- (1) Awareness – Among stakeholders to create consensus and intersect about cooling as top of the agenda particularly in view of all three internationally agreed goals that happened for the first time: The Paris Agreement; the SDGs; and the Montreal Protocol's Kigali Amendment.
- (2) More accurately defining cooling needs and targets to meet the SDGs.
- (3) A quantitative intervention roadmap and toolkit.
- (4) Cold Community Networks among stakeholders.
- (5) Cooling Services Methodology and Model – “fit for market” – including “fit for energy source” – and “fit for finance” cooling through simulation before capital intensive investment in on-the-ground deployment.

Rhetoric and Realities: Vapor Absorption Cooling System Around the Globe

Snapshots of Vapor Absorption Cooling System in Global Scenario

The global cooling market, since 1990, has been growing in excess of 4% per annum and would reach 80% by 2030 and 150% by 2050 (Saastamoinen and Paiho, 2018; International Energy Agency (IEA), 2013, 2015, 2018a, 2019a). The International Energy Agency (IEA) (2019a) estimated final energy use for cooling is to have increased by 5% globally in 2018, an exceptionally hot year in

It is also interesting to note that both the companies have higher share of their products in the capacity range of 100–200 TR but in terms of total TR of installed capacity, the highest share is assumed by 500–1000 TR VACs as indicated also in Fig. 14.

- CO₂ emission reduction opportunities through utilization of VACSs

Even as solar and wind posted double digit growth, demand for all fuels increased, led by natural gas. Higher electricity demand was responsible for over half of the growth in energy needs. EE saw improvement much lower than expectations. As a result of higher energy consumption in 2018, CO₂ emissions rose 1.7% last year and hit a new record, to a historic high of 33.1 Gt CO₂. While emissions from all fossil fuels increased, the power sector accounted for nearly two-thirds of emissions growth; coal use in power alone surpassed 10 Gt CO₂, mostly in Asia. 85% of the net increase in emissions was from China, India, and the United States. Emissions declined for Germany, Japan, Mexico, France, and the United Kingdom. In China, CO₂ emissions grew by 2.5%, driven by incremental use of coal in power stations and gas being increasingly chosen as a substitute for coal-based heating. In the United States, the emission reductions seen in 2017 were reversed, with an increase of 3.1% in CO₂ emissions in 2018. However, emissions in the United States remain around their 1990 levels, and 14% (or 800 Mt of CO₂) below their peak in 2000, which happens to be the largest absolute decline among all countries since 2000.

Fig. 15 Estimated contribution to the global reduction in CO₂ emissions from space cooling by country/region in the Efficient Cooling Scenario. Reproduced from International Energy Agency (IEA), 2018b. The Future of Cooling: Opportunities for Energy-Efficient Air Conditioning. Available at: https://www.iea.org/publications/freepublications/publication/The_Future_of_Cooling.pdf (accessed 12.04.19).

Global share of electricity from fossil fuels and that of cooling by VCCS are nearly 70% and more than 90% respectively. Also about 2100 TWh electricity has been reported to be used annually just for cooling purpose and without actions it could become 19,600 TWh in 2050 (International Energy Agency (IEA), 2019b; Peters, 2018). These would lead us to the following understanding:

- (1) The majority of cooling systems operating today are unsustainable and cause emissions as high as 4 GT of CO₂ in 2018, which is almost 11.8% of the global annual emission of 33.1 billion tonnes.
- (2) It is possible to drive present and future cooling needs by renewable energy in a sustainable way, among which VACSS have been found to most economical.

The results of research carried out by Fahléna *et al.* (2012) show that despite recent advances of compression chillers, which are becoming more and more energy efficient, potential for cost-effective CO₂ emission reduction by AC expansion, which is robust with regards to the different scenarios applied of energy market prices and policies, is high. While the effects on annual DHC system results are minor, an increased cooling demand may be met by generation associated with low or even negative net CO₂

emissions – as long as there is high availability of industrial excess heat in the DHC system, or if, for example, new biomass-based CHP capacity is installed, due to the avoided and replaced marginal power generation, as VACSSs need only a fraction of electricity input compared with the conventional counterpart, that is, compression chillers (VCCSSs).

Naukkarinen (2012) also showed that various EE and RE projects may not lead to similar reduction of CO₂ and energy saving. Careful considerations among options are required to achieve more CO₂ reduction than energy saving or vice versa, as per the need and economy. Peters (2018) reported that an aggressive range of technology and operational efficiency improvements can be implemented (GCI demand forecast – accelerated technology progress), then an additional 21% reduction in total sector energy consumption could be achieved by 2050 over and above the current technology improvement trajectory (GCI demand forecast – current technology progress). However, this would still leave consumption from the sector above the IEA 2DS implied energy budget for cooling (Fig. 16(A) and (B)).

Scenario of Renewable Energy Driven Vapor Absorption Cooling System in Developed Nations With Case of Finland

Saastamoinen and Paiho (2018) reported a study by European Commission in 2016 revealed that per capita cooling demand in single family house is more than double with compared with a multifamily building. As the trend moves to single family buildings, the cooling load will continue to increase in developed countries. For example, in Finland, as many as 50% of citizens lived in single family houses at the end of 2015 and since 2000, the heat-pump use has increased by 25-fold, at a rate of as high as 60,000 units annually, mostly in smaller capacity range of up to 6 kW. This indicates the people's intension to reduce the heating cost and would increase the demand of more number of cooling systems in summer but at lower cost of cooling. The cooling demand is estimated to increase from 1–5 kWh/m²/year to 6–39 kWh/m²/year in offices by 2030. The corresponding demand in residential buildings would be 0.5–12 kWh/m²/year. This will lead to a total cooling demand to go as high as 1700 gigawatt hours (GWh) in 2030 from 1300 GWh recently. A 13%–19% increment will be due to climate change in Finland. Out of this only the district cooling share was 178 GWh in total, which is the third largest in Europe after Sweden and Norway. The overall average cooling demand at present in Finland is 28 kWh/m² with a break up of 45 and 20 kWh/m² in the service sector and residential sector respectively.

In 2017, nine companies in Finland provided 223,439 MWh district cooling services to 491 customers, 65% of which were located in the capital area. The most commonly used district cooling technology has been heat pump (i.e., VCCSSs), free cooling, and absorption cooling (i.e., VACSSs) with a share of 60%, 25%, and 10%, respectively, and it is increasing. A good district cooling system can have supply/return water temperature difference of 10°C, which is typically 50°C for a good DHS, leading to about 4–5 times higher flow in the district cooling system calling for higher investment than the DHS. Moreover, in summer, energy fees are much higher than in winter and in 2014 it was 31.11 €/MWh in Helsinki and 36.42 €/MWh in Espoo. In Finland, a cooling tower is not required as the heat from chiller coolant is rejected to natural sources of cold water. The cogeneration DHS when also equipped with cooling services, are termed as tri-generation systems, which are capable of achieving higher energy performances than only cogeneration systems because of better system loading profile. Cogeneration district heating only systems would run at lower efficiency because of underloaded systems during winter. Approximately one-third of district heating is produced by biomass, which shows the potential of VACSSs driven by renewable energy in Finland. Energy saving through higher tri-generation efficiency often leads to attractive payback time when existing CHP site is integrated with absorption chiller. In addition, environmental benefits are obtained as the municipal solid waste-fired power plant is integrated with VACSSs. The losses in DHS are reported to be typically 10%–15% in less populated areas, 5%–8% in dense urban areas, and for the district cooling system within 2% of total delivered energy service.

It is also reported that absorption cooling cost is competitive with the available/existing air conditioning system in the long run, but for the much higher initial investment, its popularity would also depend on collateral benefits. However, until prices

Fig. 16 Cooling for all energy consumption and CO₂e emissions. Reproduced from Peters, T., 2018. A Cool World Defining the Energy Conundrum of Cooling for All. Birmingham Energy Institute – University of Birmingham. Available at: <https://www.birmingham.ac.uk/Documents/college-eps/energy/Publications/2018-clean-cold-report.pdf> (accessed 05.05.19).

reduce, solar thermal cooling would remain unutilized even with major cooling demand and irradiation occurring simultaneously in Finland (Saastamoinen and Paiho, 2018).

In the United States, the cost of district steam varies from \$11 to \$12/Million kJ and the cost of generating steam from solar installations (solar concentrators) needs to be compared based on future data.

- CO₂ Emission Reduction opportunities in Finland through utilization of VACSs

According to the BAU scenario, the total yearly cooling demand for buildings in Finland is going to increase from 1300 GWh to 1700 GWh by 2030 (Saastamoinen, 2018). Considering the emission factor for Finland as 0.24 kg CO₂/kWh electricity, as much as 312,000 t of CO₂ was released in 2017 and in 2030 the amount would be 408,000 t.

Scenario of Renewable Energy Driven Vapor Absorption Cooling System in Developed Nations With Case of Australia

Australia is different from most of the countries in the Northern Hemisphere as the solar radiation characteristics and seasonal pattern are different in the Southern Hemisphere. With a very sunny climate, there is high demand for air conditioning, as most of the cities have more CDD than also significant HDD (ideally suitable for VACS), air conditioning's impacts upon the electricity network and the environment threaten to affect quality of life in Australia, particularly on hot days in summer. Associated with the air conditioning's high use of energy is significant environmental pollution, namely in the form of greenhouse gas emissions with the resultant climate change impacting not only upon environment, but also health and productivity. Australia is one of the top ranked countries in active solar estimated annual yields for glazed flat plate collectors 700 kWh/m² per m², while its 400 kWh/m² per m² in Germany. Al-Zubaydi (2011) points out the huge potential for solar air-conditioning having higher demand when solar radiation is more, but the technology of using the solar thermal assisted air-conditioning system, in spite of suitability in conditions of Australia, is yet to be in focus in Australia as it is in rest of the world. The change is however favorable as new developments as well as the climate changes (50% of Australia's greenhouse gas emissions are from stationary energy, primarily electricity generation), energy prices, and other impacts urge us to call for further studies to investigate the feasibility of the solar thermal air-conditioning system in Australia. A number of cases of solar air-conditioning systems from Australia are included in Table 2.

Scenario of Renewable Energy Driven Vapor Absorption Cooling System in India

Solar energy is the most widely available renewable energy resource in India, where more VACSs applications could be new in terms of challenges and opportunities. Further if only 50% of the upcoming new cooling installations are done by VACSs and out of this 30% are operated by solar energy then the demand for capacity addition will be lessened by 8% of the present installed capacity in India (Choudhury and Ray, 2012). India is going to become the most populous nation in the world and is the fifth largest economy. Many players are striving to lead the growing VACS market in India, viz. Thermax, Voltas, IKON Technologies, Majestic Engineers, Lakshmi Air System, Happy Instruments, etc. The average SEER of conventional air-conditioning units sold in the fastest-growing markets, such as China and India, is typically around 4. Yet products available in those same markets – often at comparable prices – can have SEERs that are 50%–70% better (International Energy Agency (IEA), 2019a). VACSs has the opportunity to directly come out with higher SEER to catch the growing market.

The Energy Conservation Act 2001, amended in 2010, is much more stringent than the first version, and would have a favorable impact on the industry sector. The Perform Achieve and Trade mechanism, applicable to 866 Designated Consumers (DCs) Industrial Units in 13 sectors including larger commercial buildings, would encourage the use of VACSs particularly in cases where waste heat could suitably be utilized to meet ever-increasing cooling needs. DCs consume more than 50% of India's Energy Consumption and contribute significantly to India's growth rate of more than 7%. The Bureau of Energy Efficiency (BEE) (2018), Government of India, has taken pro-active measures in view of the above:

- Comparative Energy Consumption

CEC values for household frost-free refrigerators (mainly VCCSs) manufactured or imported during various period of 2011 till today or (would be) till 2021, as shown in Table 4 and Fig. 17 below, are calculated from the following equation, $CEC = K_{nf}$

$$* V_{adj_tot_nf} + C_{nf}$$

Where,

K_{nf} = Constant multiplier (kWh/Liter/Year)

$V_{adj_tot_nf}$ = Total adjusted storage volume for household frost free refrigerator (liter)

C_{nf} = Constant fixed allowance (kWh/Year)

Depending on the value of CEC, a product is rated on a scale of five stars (1* to 5*****) as shown in the Table 4. This is analogous to five star rating labeling in United States and some other countries.

India is poised for a spiral rise of cooling demand in the building sector for at least two reasons, viz. more than 60% of India's buildings in 2030 are yet to come up and by mid-2020s India is going to be the world's largest growth market (BP, 2019). The ECBC 2017 version is more versatile and optimistic compared with the first version released in 2007 and some of the government initiatives to keep the trajectory toward a low carbon path. VACSs need to be standardized and labeled with a suitable mechanism.

As the transport sector is getting electrified very fast, VACSs would find application in vehicles for at least three reasons, viz. VACS consume only about 1/7th of electricity needed in VACCs of same capacity, solar radiation and cooling demand match each

Table 4 Star level valid in India for household frost free refrigerator from January 1, 2020 to December 31, 2021

Sl. No.	Star rating band during this period	Comparative Energy Consumption (CEC) criteria	Star rating band in immediate past period
(1)	(2)	(3)	(4)
1.	1 Star *	$(0.228 * V_{adj_tot_nf} + 199) \leq CEC < (0.286 * V_{adj_tot_nf} + 249)$	2 Star **
2.	2 Star **	$(0.183 * V_{adj_tot_nf} + 159) \leq CEC < (0.228 * V_{adj_tot_nf} + 199)$	3 Star ***
3.	3 Star ***	$(0.146 * V_{adj_tot_nf} + 127) \leq CEC < (0.183 * V_{adj_tot_nf} + 159)$	4 Star ****
4.	4 Star ****	$(0.117 * V_{adj_tot_nf} + 102) \leq CEC < (0.146 * V_{adj_tot_nf} + 127)$	5 Star *****
5.	5 Star *****	$CEC < (0.117 * V_{adj_tot_nf} + 102)$	Much superior

Fig. 17 Identification of applicable star (*) rating of household frost free refrigerators in different periods from January 2009 to December 2021.

other in vehicles, and more stringent environmental norms would be in favor of VACSs. Green mobility mission sets a target of at least 50% electrification of all vehicles on the road by 2030.

MNRE Government of India (2019) has set a target of 175 GW electricity generation capacity from solar (100 GW), wind (60 GW), biomass (10 GW), and small hydro (5 GW) from renewable sources by 2022 when India's electricity demand is estimated to be double that of 2011–2012 value and has reported that about 40% of the target has already been achieved. However, this is low in view of solar energy potential of 750 GW and wind potential higher than 1000 GW. Total electricity generation capacity of 275 GW is significantly higher than India's peak demand of 177 GW. Energy sector, with more than 60% electricity coming from that of coal-based thermal

power plants alone, is the largest contributor to CO₂ emission among all sectors in India. Renewables along with EE are going to play an important role in fulfilling India's commitment to reduce energy intensity by 20% with compared with 1990 level by 2020.

International Energy Agency (IEA) (2018b) observed that the deployment of solar PV in India is expected to grow strongly, up to 1000 GW of installed capacity by 2050. This means there will more often be times when more power is being generated than is required, leading to curtailment of excess PV generation during the sunniest times of the day, which has already been experienced by Germany. As India's growth of cooling demand is being influenced more by the residential sector, typically peaking in the early evening around 7 p.m., when the sun has gone down and solar PV is no longer providing its full capacity, one potential way to address this mismatch is to store cold and then distribute it to buildings through district cooling networks. For instance, heat pumps could produce chilled water or ice when the solar electricity is available, and then use that storage to meet cooling loads later in the evening. To demonstrate the potential benefits of using thermal storage with solar PV and integrated district cooling, the operation of the Indian power system was modeled during a peak cooling week in 2050. The simulation considers a scenario in which India's cities – where the expected growth of cooling demand will be concentrated – would use district cooling networks with thermal storage to partially meet cooling loads from ice or chilled water produced using daytime solar PV. The scenario does not suggest that district cooling would be economically viable in all Indian cities; rather, it provides a sense of the potential and magnitude of the thermal storage needs to meet rapidly growing peak cooling demand in India through the country's large solar generation potential. The model assumes a total thermal storage of 2400 GWh thermal, corresponding to an equivalent of about 600 GWh of electrical storage. The IEA estimates that roughly one-fifth of the total solar PV output could be stored during the day as chilled water or ice, which otherwise would be curtailed and hence lost. That cold storage could then be discharged later in the evening, meeting around 15% of space cooling demand after the sun goes down. The required volume would be comparable to around 20,000 Olympic-sized swimming pools (if the storage medium were ice). Discharge from such a system could meet peak cooling demand between 5 p.m. and 7 p.m., while equally reducing the need for peak generation capacity (e.g., using coal- or gas-fired thermal power generation, shown in dark blue). The model results show a reduction in peak residual demand of 11%, or 80 GW. In addition, the thermal storage adds system flexibility through balancing of supply and demand, which allows provision of electricity from cheaper generation sources throughout the year. Estimates of total system costs reveal a net savings from the use of energy storage to meet cooling loads through excess PV generation, compared with a scenario without storage requiring more peak power generation. The estimated annual system savings are higher for thermal storage (USD 9.7 billion) than battery storage (USD 7.5 billion). This is the result of lower costs for thermal storage capacity at around 10 USD per kWh thermal compared with targets of around USD 300 per kWh electric for battery storage in 2050. Those savings would likely outweigh additional costs for the district cooling system (e.g., network pipes and substations), given the long life of typical district energy networks and investments that can be amortized over time. Of course, the more efficient the AC stock is, the lower the investment is required. While this analysis does not provide a detailed assessment of the specific local conditions or system dynamics that would be required for sound energy system planning and investments, it does suggest that combining different supply and demand-side elements could offer cheaper, cleaner, and more flexible solutions to meet space cooling demand in India. These types of integrated solutions, allowing for greater use of renewable energy sources, could also complement broader economic and social policy objectives – for instance, cutting local air pollution from electricity generation. Thermal storage could take advantage of surplus solar output to alleviate the strain of peak cooling demand on the electricity system in the evenings. Thus, thermal storage could take advantage of surplus solar output to alleviate the strain of peak cooling demand on the electricity system in the evenings.

Aggregate consumption of the commercial sector, growing at 12% annually, stood at 70 TWh in 2012, of which HVAC, lighting, and others comprised 55%, 25%, and 20%, respectively. The relevant quantities are shown in Table 5 (NITI Aayog, 2015) emphasizing the indispensability of VACS driven by renewable energy for this largest democracy in the world.

- CO₂ Emission Reduction opportunities in India through utilization of VACSs

Sachar *et al.* (2018) observed that, with world's largest growth market for cooling, India's cooling-related energy demand from RACs increased 20-fold from just 94 TWh (out of total generation of 938 TWh, that is, almost 10% of total) in 2016 to 1890 TWh in 2050 and thus the country emerges to become the world's largest energy user for space cooling in 2050. The per capita energy use for space cooling from RACs increases from mere 72 kWh (one of the lowest in the world) to 1140 kWh owing to rapid urbanization and a growing affluent middle class that desires a better quality of life and health. India would and need to benefit significantly from the adoption of the 5× solution, that is, five times improvement in EE, adoption of which could reduce India's estimated peak loads by around 400 GW in 2050 while resulting in the curtailment of about 1300 TWh required to operate these units – Almost equivalent to India's total electricity consumption today. Thus, by 2050, India's avoided cumulative emissions would be 16 Gt, which essentially neutralizes the climate impact of total carbon dioxide emissions (from primary energy) of the country over the last decade, and would play an important role to achieve the Nationally Determined Contributions (NDCs) in line with the Paris climate goals and reduce the emission intensity of the Indian economy by 15% in the year 2030 (from 2005 levels) – nearly 40% of the NDC target. This, when combined with the country's renewable energy target of 175 GW by 2022, could achieve a 48% reduction in the emissions intensity, putting the Indian economy on a sustainable pathway. It may be noted that India's air conditioner minimum efficiency performance standards program led by BEE saw an efficiency increase of 30% from 2006 to 2016, 2015, while prices dropped by 20%. As more than 60% of electricity generated in India is from coal, the emission factor is as high as 0.82 kg CO₂/kWh, which means HVAC in the commercial sector alone is responsible for an annual emission of 90 billion tons of CO₂ in India, which is more than 10% of total annual emission, that is, 888 Mt in 2016–2017.

Table 5 Potential of demand reduction from determined effort scenario to heroic effort scenario for India

Sectors	Sector demand in 2012 (TWh)	Demand in 2047 (TWh)			Policy response

Fig. 18 Illustrative analysis of the potential role of storage using solar photovoltaic for district cooling over two days in April 2050 during the peak cooling period in India. Reproduced from International Energy Agency (IEA), 2018b. *The Future of Cooling: Opportunities for Energy-Efficient Air Conditioning*. Available at: https://www.iea.org/publications/freepublications/publication/The_Future_of_Cooling.pdf (accessed 12.04.19).

The International Energy Agency (IEA) (2019a) pointed out that the Cooling Action Plan, being released in 2018, is the first of its kind in the world and has put forth multiple proposed interventions to address cooling across multiple sectors, following 2018 updates to India's Seasonal Energy Efficiency Ratings (ISEER), which took effect in January 2018. The full version available at website provided in "Relevant Websites section" is said to be in draft form, not to be cited. The Press Information Bureau' (PIB) released the main highlights, which include to look for synergies in actions for securing both environmental and socioeconomic benefits. "The overarching goal of ICAP is to provide sustainable cooling and thermal comfort for all while securing environmental and socio-economic benefits for the society, acknowledging the SDGs. This will also help in reducing both direct and indirect emissions" and aims to provide an integrated vision toward cooling across sectors encompassing inter alia reduction of cooling demand, refrigerant transition, enhancing EE and better technology options with a 20 year time horizon. The India Cooling Action seeks to (1) reduce cooling demand across sectors by 20%–25% by 2037–2038, (2) reduce refrigerant demand by 25%–30% by 2037–2038, (3) reduce cooling energy requirements by 25%–40% by 2037–2038, (4) recognize "cooling and related areas" as a thrust area of research under the national S&T Programme, (5) provide training and certification of 100,000 servicing sector technicians by 2022–2023, synergizing with the Skill India Mission. According to PIB, the following benefits would accrue to the society over and above the environmental benefits: (1) thermal comfort for all – provision for cooling for EWS and LIG housing; (2) sustainable cooling – low GHG emissions related to cooling; (3) doubling farmers income – better cold chain infrastructure, better value of produce to farmers, less wastage of produce; (4) skilled workforce for better livelihoods and environmental protection; (5) make in India – domestic manufacturing of air-conditioning and related cooling equipment; and (6) robust R&D on alternative cooling technologies – to provide push to innovation in cooling sector (Fig. 18).

Conclusion and Way Forward

A number of studies reported in literature are based on simulation and/or laboratory experiments and reveal huge opportunity but point to needs for practical actions to bring the benefit to market as early as possible as the cooling demand is increasing at one of the highest rates among all energy guzzling sectors globally. In response, achieving LCE in cooling through EE and RE would mean

a step toward survival of our civilization threatened by rupture in energy supply and energy demand in the near future, climate change crossing dangerous limits and unstable social-economic structure in many parts of the globe, all three being anthropogenic in nature.

Many of the innovative ideas are yet to come and have the potential to leap-frog the drive, a few being discussed in this article, such as, employing DAP, to operate in PEx mode, drastic improvement of SEER, innovative policy, MCDM, standardization and labeling and VCCS–VACS hybrid driven by renewable power, DH to tri-generation, and so on, with practical examples.

The multiple benefits of VACSs are far from being considered in the purchase and policy decisions at the micro and macro level respectively. Renewable energy driven VACSs bring energy security, environmentally benign non-CFC refrigerants, lowered/abolished CO₂ emission to run the cooling system, reduced/abolished electricity consumption for cooling, and an attractive economy particularly where heat is otherwise wasted/underutilized.

The voice is far and wide through various landmark initiatives, such as, 100%RE, Kigali tracker under its Global Exchange Platform to work with countries and K-CEP partners, Technology Collaboration Programs (TCPs), Cooling Action Plan (in India) – The first of its kind in the world and ‘First-ever global coalition for clean cooling’ by the United Nations. Though well-taken, such global intentions need head and heart to join with hands for practical actions by all local stakeholders to achieve the goal.

Acknowledgment

The authors would like to express sincere thanks and gratitude to Prof. Dr. Rajagopal Dhar Chakraborti, Director and Prof. Dr. K.M. Agrawal, former Dean (Academics) of Indian Institute of Social Welfare & Business Management (IISWBM) for continuous encouragement and support to complete this article in spite of delay and dilemma due to academic and professional commitments to jobs at different parts of the globe.

Sincere acknowledgment is also to the respective institutions and family members, Rhitambhar (Rio), in particular, for without their support and sacrifice, this work would not have been completed.

Eco-Sustainable Molecular Quantum Dot Cellular Automata Based Radiography in Defect Identification of Industrial Product Using Renewable Energy Source

Paramartha Dutta, Visva-Bharati University, Santiniketan, India
Debarka Mukhopadhyay, Adamas University, Kolkata, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

From the last century fossil fuel, combustion of coal had been fundamental drivers of industrial revolution which lead to technological, social, economic progress globally. These energy sources have negative impacts on environment being dominant sources of carbon dioxide, carbon monoxide and other greenhouse gases. Hence it has become imperative to decarbonize and minimize dependence on coal and fossil fuel and transition towards renewable energy sources.

India currently started relying and building infrastructure on renewable energy sources. It is Electricity sector utilized renewable energy (excluding large hydro) for 20% of the total installed power capacity (71.325 GM) as on 30 June 2018 (Anon). India is the fourth largest wind power in the world having capacity of 34,046 MW as on 31st March 2018. The country is already having strong manufacturing base in wind power with international quality and exporting wind turbine models to other countries (Anon1).

Government of India has taken a big initiative by taking target of achieving 100 GW of solar power by 2022. Second largest solar park in the world is established at Kurnool, Andhra Pradesh, with a capacity of 1000 MW. The country has also four of the top seven largest solar parks worldwide (Anon; Anon1). In our current contribution we avail this opportunity to propose a methodology that enables us avoiding combustion of non-renewable energy such as fossil fuels and using power generated through renewable energy source such as sunlight to run Quantum Dot Cellular Automata based industrial radiography system.

The proposed methodology incorporated here with Quantum dot Cellular Automata paradigm consumes very small amount of power and energy to radiate gamma ray of similar intensity. The present invention relates to Molecular Quantum dot Cellular Automata methodology to electronically radiate gamma rays for industrial radiography system from QCA cell unit.

Discovery of Gamma Rays in the year 1900 by a French chemist and physicist, Paul Villard revolutionized many industrial applications including locating the cracks or flaws in materials such as Gas and oil pipelines, Metal welding, Boilers, Vehicle parts and Aircraft parts etc., such cracks typically are not visible from the outside without damaging the material. The existing convention for production of Gamma Ray (Jacques *et al.*, 1975a; Schneeman, 1944; Pellechia, 2016; Van, 1975; Jacques *et al.*, 1975b) can not turn off the production of the ray when the system is not in use. The radioactive material always produces gamma rays. The only way there to prevent the gamma beam is to place a heavy metal plate at the opening of the device. So worker has to remain very careful even when the device is not in use to avoid exposure. Gamma ray is pointed to the item under consideration. On the other side of the item a detector is lined up. A thick item allows fewer amount of gamma ray to pass through it. Area with crack or flaws allow greater amount of gamma ray to pass through. Detector captures gamma ray and form picture of cracks.

This is worth mentioning that a mathematically monotonic relation seems prevalent while relating voltage consumption and power consumption with generation of greenhouse gas. But to the best of our knowledge, there is hardly any established equation relating this three parameters. As such any device with lesser power/energy requirement is more desirable from the perspective of greenhouse effect. Less the power/energy consumption is, the more environment friendly the device would be. This is primarily because the major source of energy is combustion of fossil fuel and carbon source, in the present day scenario. Accordingly a low power device based on nanotechnology stands in good stead from environmental point of view. Our present proposal appears meritorious in this context.

We shall first analyze the technical feasibility of fabrication of metal dot QCA using electrometer. Accordingly, we ascertain whether it is possible to achieve the same at room temperature. The study in the next three sections establishes that the radius of graphene based metal dot will be in attometer dimension only which is not possible to fabricate in respect of available technology.

The present invention relates to Molecular variant of Quantum dot Cellular Automata methodology for generating gamma ray wave from QCA unit.

Consideration of SET to Determine the Radius of Island of Metal Dot QCA

4 dot 2 electron metal dot QCA is fabricated using single electron transistor due to associated advantages like small size, low power consumption, and ability to perform fast and sensitive charge measurements (Liu *et al.*, 2002; Visconti *et al.*, 2004). Fig. 1 (Visconti *et al.*, 2004; Lu *et al.*, 2006) depicts the schematic of the metal dot QCA realization.

Fig. 2 (Visconti *et al.*, 2004) indicates SET circuit which comprises a dot between the Source and Drain electrodes. The island is separated from these electrodes by a tunnel junction. Each tunnel junction has its resistance and capacitance as shown in Fig. 3. The dot is also capacitively coupled to the Gate electrode which also has a capacitance to regulate current flow. The total capacitance (C) between the dot and outer environment is given below:

$$C = C_1 + C_2 + C_g \quad (1)$$

Fig. 1 Simplified schematic of the four-dot QCA cell and electrometers.

Fig. 2 Single electron transistor.

Fig. 3 Tunnel junction.

C_1 , C_2 and C_g denote drain capacitor, source capacitor and gate capacitor respectively. Three conditions need to be met to achieve coulomb blockade.

- (1) $V_{bias} < \frac{e}{C}$
Here V_{bias} denotes bias voltage, e denotes elementary charge and C denotes total capacitance.
- (2) $R_t > \frac{\hbar}{2\pi e^2}$
Here R_t denotes the tunneling resistance and $\hbar$ is plank's constant. This condition is derived from Heisenberg's uncertainty principle.
- (3) $KT < \frac{e^2}{2C}$
Here KT denotes the thermal energy, $K = 1.3806505 \times 10^{-23}$ J/K, $\frac{e^2}{2C}$ denotes the charging energy or coulomb energy and T is temperature. If this condition is not met then the electron will pass the quantum dot via thermal excitation. When one electron overcomes the charging energy and tunnels into the quantum system, it blocks the tunneling of a second one since it would charge additionally the quantum system by an amount $< \frac{e^2}{2C}$. The effect is that a single electron may tunnel through at a time.

In **Fig. 4** the region $-\frac{e}{2C} < V_{dc} < \frac{e}{2C}$ is called coulomb blockade region, with a coulomb gap voltage V_{gap} . In this region the electron's energy is smaller than the repulsive Coulomb energy of the electrons on the island.

Fig. 4 The stability charge diagram of the source-drain voltage, V_{ds} , across a SET as a function of the gate voltage V_g . The gray regions have zero source-drain currents I_{ds} (Coulomb blockade regions).

Fig. 5 (a) an electron feeling a small attractive force as it approaches a sphere. (b) Once sphere gets charged negatively by a single electron; other electrons will feel a strong repelling force.

Determining the Radius of Island in Room Temperature

In SET the island can be explained by assuming a small metallic sphere, as shown in **Fig. 5**. This island is initially electro-neutral i.e., the net charge on this island is zero since the number of electrons and protons are same in it. Now, consider that a single electron is placed close to the island. In this situation, it gets attracted towards the island. Thus, this single electron comes into the island and leaves a negative charge of e on it. Now, due to the presence of this negative charge, an electric field is created around the island so that in the event of another electron approaching close to this island, it will face a strong repulsive force induced by the electric field created around the island (Lent, 1997; Lent *et al.*, 1993; Lent and Tougaw, 1993).

The total capacitance (C) corresponds to the self capacitance of island. When the island is a sphere with a radius of R embedded in a dielectric material with a dielectric constant, the self capacitance, (Lent, 1997; Lent *et al.*, 1993; Lent and Tougaw, 1993) is given by

$$C_{\text{self}} = 4\pi\epsilon_0\epsilon_r R \quad (2)$$

Where ϵ_0 and ϵ_r are permittivity of free space and permittivity of dielectric material of capacitor. From the 3rd condition we get $C < \frac{e^2}{2kT}$. Therefore at room temperature (300°K) $C < 3.09 \times 10^{-18}$ F.

Here we use graphene as a metal of island primarily because it is a good conductor. In the 5–40 GHz range encompassing the microwave and the lower part of millimeter wave spectrum, the electrical permittivity of graphene is almost 3 (Toth and Lent, 1999). This experiment was carried out using a coupled coplanar wave guide placed over a graphene mono layer flake, which is deposited on Si/SiO₂. So the relative permittivity of graphene is 3.3882×10^{11} . Now from Eq. (2) we can write,

$$4\pi\epsilon_0\epsilon_r R < 3.09 \times 10^{-18} \text{ F} \quad (3)$$

Thus, $R < 0.819721$ Attometer

Here we performed studies for the radius of island in room temperature. It is seen from Eq. (3) that the radius of island will be in attometer range which is not possible to fabricate using graphene as a metal.

QCA Cell and Molecular Cell Clocking Arrangement

The QCA cell and electromagnetic clock signal are the most vital ingredients in the invention of gamma-rays radiated from QCA cells which consume very less amount of electric energy and power.

Fig. 6 QCA cell in V shaped molecular form. Reproduced from Anon2, Siemens oem products, www.siemens.com/healthcare. Karim, F., Walus, K., Ivanov, A., 2010. Analysis of field-driven clocking for molecular quantum-dot cellular automata based circuits. J. Comput. Electron. 9, 16–30.

Fig. 7 Molecular cell dimension.

QCA Cell

Each cell is composed of two V shaped molecular structures and has six redox sites. as shown in Fig. 6. The redox sites are considered as quantum dots. The figure depicts three stable configurations of the two mobile electrons within the molecular cell. Mobile electrons establishing themselves at the upper diagonal sites (i.e., either at sites 2 and 0 or 1 and 3) represent ACTIVE states of the cell. These active states carry two polarities of the cells viz. $P = \pm 1$. $P = 1$ is said to represent binary '1' and $P = -1$ represents binary '0'. When the two mobile electrons are positioned at the two sites depicted below, the cell is said to represent 'NULL' state. Fig. 7 indicates molecular cell dimension. Here we employ cell size (d) to be 1 nm and height (h) to be 1 nm (Karim *et al.*, 2010; Lent and Isaksen, 2003; Lu *et al.*, 2006).

Molecular System Clocking Arrangement

Clock signal is applied through submerged electrodes buried in oxide layer (Anon2).

Managing Electrodes

The electrodes carry electromagnetic clock signals and they are placed at the bottom of the oxide layer. The phase shifted sinusoidal signal is applied to each of the electrodes to energize the electrons. Fig. 8 depicts the four phases of the applied sinusoidal signal viz. ϕ_1 , ϕ_2 , ϕ_3 and ϕ_4 with $\phi_1 < \phi_2 < \phi_3 < \phi_4$ such that the data may flow in the direction as indicated in Fig. 8. This electric field

Fig. 9 Submerged electrodes to generate an electric field $\vec{E}$ at the level of molecular cells. Reproduced from Anon2, Siemens oem products, www.siemens.com/healthcare.

Fig. 10 The figure on the left side shows perspective view of two buried electrodes. The figure also shows the ground plate and the electrodes are buried within oxide. The figure on the right is a cross sectional view of the figure on the left. Reproduced from Karim, F., Walus, K., Ivanov, A., 2010. Analysis of field-driven clocking for molecular quantum-dot cellular automata based circuits. J. Comput. Electron. 9, 16–30.

$\vec{E}$ in the Y and $-Y$ directions switch the molecular cell from ACTIVE state to NULL state and vice-versa. The electrodes have finite radius and potential voltage is applied with respect to grounded plate as per Fig. 9. Average electrode potential (Anon2) is determined as,

$$V_{avg} = \frac{V_{e1} + V_{e2}}{2} \quad (4)$$

where V_{e1} and V_{e2} are the potentials on two adjacent electrodes. The electrode potential difference between these two adjacent electrodes can be given as,

$$\Delta V_e = |V_{e2} - V_{e1}| \quad (5)$$

The RMS voltage V_{rms} can be defined as $\sqrt{(V_1^2 + V_2^2)}$. Where V_1 is maximum allowable V_{avg} and V_2 is minimum allowable V_{avg} (Anon2).

The interdependence between cell size and RMS voltage is studied and analyzed in Fig. 10. A spacing of 20 nm (Anon2) is applied while selecting V_{rms} and cell size. While selecting the above two parameters we need to analyze the temperature issues also.

Now maximum applicable phase difference ϕ_{max} between two adjacent electrodes having maximum potential difference ΔV_{emax} can be expressed as,

$$\phi_{max} = \pm 2\sin^{-1}\left(\frac{\Delta V_{emax}}{2V_0}\right) \text{ radians} \quad (6)$$

Here, V_0 is peak potential value of clock signal applied to adjacent electrodes and the minimum RMS voltage should be applied (Anon2; Karim *et al.*, 2010). The inter-electrode spacing is maintained at 20 nm. The ground plate is placed $\eta = 25$ nm above the electrodes and cells are placed $\beta = 23$ nm above the electrodes as depicted in Fig. 10. The length and radius of electrode are chosen to be 100 nm and 5 nm respectively as justified in Lu *et al.* (2007), Visconti *et al.* (2004) and Dutta and Mukhopadhyay (2019). Dielectric like SiO_2 is used between electrodes and molecules whose dielectric constant is 4.2. The electrodes shall be buried inside the dielectric (SiO_2) (Liu *et al.*, 2002).

Gamma-Ray Generation Methodology for Portable Industrial Radiography System

Tunneling electrons exhibit dual wave particle behaviour. During the act of tunneling, electrons attain the nature of sinusoidal wave (Fock, 1986) as supported in Born's Probabilistic Interpretation (Timler and Lenta, 2002). It demonstrates "particle has a greater probability of being found near $x = 0$, i.e., at dots and reduces chance of being found away from $x = 0$ ". At dots electrons behave as particles. The electron wave ($\psi(x)$) tunneling through the positive X direction with associated finite potential energy $V(x)$ can be represented using time independent Schrödinger wave equation as given in Eq. (7) below,

$$\frac{d^2\psi(x)}{dx^2} + \frac{2m}{\hbar^2}(E - V(x))\psi(x) = 0 \quad (7)$$

where, E is discrete energy of an electron. m is mass of an electron and $\hbar$ is reduced plank constant. This equation (Fock, 1986) reduces to

$$E_n = \frac{\pi^2 n^2 \hbar^2}{2md^2} + V(x) \quad (8)$$

where E_n is infinite sequence of discrete energy levels corresponding to all possible nonnegative integral values of n , the electron quantum number and d is molecular cell dimension. Electrons acquire energy from the applied clock and jump up to higher energy state. On the contrary, while losing energy they move down to lower energy state. Movement of electrons from higher to lower energy levels leads to radiation of energy. This radiation is of our interest and it is tuned to generate Gamma ray for industrial radiography system. The transitions between these energy states are possible if sum or difference of quantum numbers is an odd number (Orlov *et al.*, 1997; Anderson, 1979; Baym, 1969; Fock, 1986). Transitions are strictly forbidden if both the quantum numbers are even (Orlov *et al.*, 1997; Anderson, 1979; Baym, 1969; Fock, 1986).

Any transition of an electron from higher energy state (n th state) to ground state can be expressed with the help of Eq. (9) as,

$$\Delta E_n = \frac{\pi^2 \hbar^2}{2md^2}(n^2 - 1) \quad (9)$$

Industrial radiography system (Jacques *et al.*, 1975a) requires Gamma ray energy in the range of 1.24 MeV. Considering this energy radiation i.e., 1.24 MeV and equating it to ΔE_n in Eq. (9), the relation between electron quantum number n and molecular cell dimension d can be expressed as,

$$1.65 \times 10^{24} d^2 = (n^2 - 1) \quad (10)$$

A careful study of Fig. 11 reveals that at temperature of 1200°K and at 2.12 V_{rms} operating voltage the cells attain a dimension of 1 nm. If molecular cell dimension is considered to be 1 nm, Gamma ray radiation for radiography system, Eq. (10) produces the

Fig. 11 The plot depicts a trade off between maximum operating temperature in K, cell size in nm and RMS voltage in volt. Reproduced from Anon2, Siemens oem products, www.siemens.com/healthcare.

Table 1 Comparative study on existing and proposed molecular QCA industrial radiography system

Technical specifications	Existing technology	Proposed technology
Power supply	Not applicable	2.12 RMS Voltage
Operating temperature	Normal temperature	1200°K
Power generation	Not applicable	In the range of Watt
Transformer	Not applicable	Step down supply
Compact cooling system	Not required	Required
Radiation	Not controllable	Controllable

value of n to be 1286. For a single molecular cell Eq. (9) can be reformed as,

$$\nu_2 = \frac{\pi \hbar}{2md^2}(n^2 - 1) \quad (11)$$

where, ν_2 is radiation frequency.

Eq. (11) produces a result of 300.73×10^{18} Hz with $n = 1286$ and $d = 1$ nm, which falls within the frequency range of existing Gamma ray for Industrial radiography system. Expression in Eq. (8) should be greater than or equal to $\frac{CV^2}{2}$, where C is barrier capacitance and V is applied voltage (Fock, 1986). A voltage of $2.12 V_{RMS}$ is applied to a barrier capacitance of 0.043 pF and this voltage is enough to cross the barrier. The above calculations are for single molecular cell. The radiation energy strength for N number of molecular cells arranged in cascade is computed as 1.24×10^6 N eV.

Proposed Gamma-Ray Generator for Industrial Radiography System

Our present disclosure is the Gamma ray generating part of Industrial radiography system. The existing Gamma ray generator works without electricity and radiates all the time even when the device is not in use. Whereas the current disclosure works at $2.12 V_{RMS}$ supply, consumes power in the range of Watt only and running at an operating temperature of 1200°K and is able to be electrically switched off the radiation (Table 1).

Proposed QCA Based Gamma Ray Industrial Radiography System

The primary unit of our proposed system is a Gamma-ray plate containing an array of molecular cells arranged in sequence as shown in Fig. 12(a). Each cell in the plate may be replaced by the molecular counterpart as shown in Fig. 12(b). Fig. 13 depicts the electrodes at the bottom of the section. They are buried under SiO_2 layer. The molecular cells are arranged over the layer as they are

Fig. 12 (a) Gamma-ray plate containing an array of square cells. (b) Molecular cell that will replace the square cells in Gamma-ray plate. h is cell height and d is cell dimension.

Fig. 13 Cross section view of the proposed Gamma-ray generator Unit for Gamma Ray Generation.

arranged over the plate. One grounded plate is placed above the cell level. All the molecular cells are having a size of 1 nm. It may work at temperature of 1200K and execute at an applied voltage of 2.12 RMS voltage. This value of RMS voltage might be supplied to the electrodes buried under the dielectric through step down transformer. The Gamma-ray generator in Fig. 13 is housed within the Gamma-ray radiography system as in Fig. 14. It contains a power supply section at the bottom, Gamma ray plate as in Fig. 12(a). The power supply section is consisting of electrodes, oxide layer and grounded plate. The Gamma-ray generator runs at a temperature of 1200K. So there is need to control the temperature inside. Our contribution here is the molecular QCA Gamma-ray tube that runs on electricity, runs in 1200K temperature, execute with the supply voltage of 2.12 RMS Voltage and no radiation while switched off.

Fig. 14 Quantum dot cellular automata based industrial radiography system.

Conclusion

The article discloses a proposal of nature friendly Gamma-ray generating system used for the purpose of industrial radiography. This technology can be operative by consuming energy generated from harness natural processes such as geothermal energy, wind energy, biomass energy, solar energy, hydro-electric power etc., for system execution. Existing industrial radiography solution technologies being typically power hungry seem unsuitable for use of such eco-friendly power generating sources. The nano-technology based system places itself as appropriate from environmental point of view. As a result it may be found to eliminate any chances of generation of greenhouse gases and keeps the environment clean and worth living.

Fermentative Production of Optically Pure Lactic Acid From Renewable Materials

Shubhalakshmi Sengupta, Papita Das, and Siddhartha Datta, Jadavpur University, Kolkata, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

It is well known that in the coming years of globalisation of commodity products due to rise in human consumption will result in depletion of the planet's natural reserves. The use of the unsustainable natural resource, crude oil leads to an increase in carbon dioxide (CO₂) and methane (CH₄) in the environment (Sukan *et al.*, 2015). Again, worldwide the plastics that are used nowadays are synthesized from these fossil fuels and their depletion after use from the environment will take great amount of time and will be hazardous for the planet (Chen and Patel, 2012; Blanco *et al.*, 2011, 2013, 2014).

Since, plastics or rather polymers have become an important part of our lives various technologies are used to improve it and make it more environment friendly. But with the depletion of its source materials novel resources are being sought after. Along with scarcity of resource with polymer production a great deal of its usage results in increase of atmospheric greenhouse gases (GHGs). This results in global warming and increase usage of this non-renewable resource increases the carbon footprint as well (Hottle *et al.*, 2013; Colwill *et al.*, 2012). These escalating environmental problems over the recent years have led to the microbial synthesis of commercially valuable products, i.e., by adopting "green methods" (Abdel-Rahman *et al.*, 2013). Emission of greenhouse gases (GHGs) and increase in the carbon footprint have driven the world towards adopting such techniques. The urge for the synthesis of biopolymers have lead to a search from "green chemicals" from renewable resources (Flieger *et al.*, 2003; Du and Yu, 2002; Landis *et al.*, 2007).

It is well known, that lactic acid (LA) is a commercially important chemical product owing to its wide application in various industries like cosmetic, food, pharmaceutical and chemical industries. Nowadays LA is used in the synthesis of the polymer poly lactic acid (PLA). PLA has great potential in production of various products ranging from fibers to foam (Abdel-Rahman *et al.*, 2013). In global estimates demand for PLA was 360.8 kilo tons in 2013 which is assumed to grow upto 18.8% by 2020 and reach 1960.1. Consequently, in 2013, 714.2 kilo ton of LA was produced which is could reach 1205.3 kilo ton by the year 2020 with a growth rate of 15.5% (Abdel-Rahman *et al.*, 2013; Abdel-Rahman and Sonomoto, 2016). LA production is generally achieved through two routes (i) chemical synthesis and (ii) fermentative routes. Chemical synthesis is done mainly by the hydrolysis of Lactonitrile which produces a racemic mixture of D-(-)- LA and L-(+)- LA. The fermentative production produces optically pure D-(-)-LA or L-(+)-LA when the suitable microorganism is used for the synthesis of Lactic acid through fermentative routes. This results in use of substrates from renewable resources. At present most of the lactic acid produced in the world comes from this fermentative routes. About 90% of LA is produced through this fermentative route (Okino *et al.*, 2008; Abdel-Rahman *et al.*, 2013; Abdel-Rahman and Sonomoto, 2016). Thus, for the production of optically pure lactic acid, suitable biotechnological innovations are required. Lactic acid production through fermentative route has been done mainly from sugar substrates like glucose, lactose, maltose, sucrose etc., procured from barley, malt, molasses and beet sugar.

However, production of lactic acid from economically viable resources such as rice bran, green microalga and paper sludge have also been achieved (Wang *et al.*, 2015). In recent times lignocellulosic starch from agricultural residues and also from forest materials have been sought by researchers for synthesis of lactic acid (Wang *et al.*, 2015). Wide arrays of microorganisms have been used applying various optimum conditions to achieve the desired results by the researchers for production of optically pure lactic acid. Among the microorganisms commercially important lactic acid bacteria i.e., lactobacillus have been used mostly. These strains are advantageous due to their ability of high acid concentration tolerance. They are also able to generate selective synthesis of optically pure D-(-)-LA or L-(+)- LA through genetic engineering. However, they possess disadvantages such as requirement for complex nutrients and little pentose utilization (Zhou *et al.*, 2003). Other microorganisms used for this purpose include *Rhizopus*, *Escherichia*, *Saccharomyces*, *Bacillus* and *Kluyveromyces*. These microorganisms require improvements in substrate range for improved productivity and enhanced optical purity of the product (Zhou *et al.*, 2003; Saitoh *et al.*, 2005). However, there are various constraints in LA production, such as most of the substrates requires pretreatment of its renewable source due to removal of lignin and lack of hydrolytic enzymes in LA producing strains. Purification of LA from broth is also a concern. So such challenges are persistent in production of optically pure LA.

Lactic Acid

Lactic acid in recent times have emerged as a great product for production of various industrially desirable materials and also for the production of bioplastics from renewable resources. Lactic acid (2-hydroxypropanoic acid) is a hydroxycarboxylic acid which occurs naturally and present in L form in humans. Swedish chemist Scheele in the year 1780 first refined it from sour milk. Then it was used majorly in the food industry for enhancing flavour, as an acidulant and also as a preservative. Gradually it emerged as an important chemical to be used in cosmetic, pharmaceutical and chemical industries. Recently its use for synthesis of PLA has been widely sought for. Among, the optical isomers of lactic acid L-(+)- LA is preferred in drug and food industries as this form of LA could be easily assimilated in human body. Copolymerisation of both the isomers leads to an amorphous structure whereas homopolymers are crystalline in nature having regular structures (Wang *et al.*, 2015).

Synthesis of Optically Pure Lactic Acid

As discussed earlier there are two routes for the synthesis of optically pure LA. However, batch fermentation method is the widely used for LA synthesis. The conditions for the fermentation processes are different as per their industrial requirements. For example, in case of organism *Lactobacillus delbrueckii*, LA is produced at temperature range of 45–60°C within a pH range of 5–6.5 whereas when *Lactobacillus bulgaricus* is used temperature is maintained at 43°C within a pH 6–7. LA synthesized by batch fermentation has a yield of 90%–95% based on initial substrate concentration and depending on various parameters of pH, concentration of nitrogenous nutrients, temperature and initial substrate concentration (Ghaffar *et al.*, 2014; Meng *et al.*, 2012).

Chemical Synthesis of Lactic Acid

As discussed earlier, lactonitrile is used for the chemical synthesis of LA. Lactonitrile is synthesized by adding hydrogen cyanide to acetaldehyde at high atmospheric pressure. The synthesized lactonitrile is purified by distillation followed by hydrolysis by concentrated H₂SO₄/HCL to get the desired LA and the ammonium salt. Then it is esterified by methanol to form methyl lactate and further purified before second hydrolysis to form LA and methanol. Consequently, a racemic mixture of L and D-LA is formed (Ghaffar *et al.*, 2014).

Fermentative Synthesis of Lactic Acid

Fermentative synthesis is the most preferred route. It is an energy generating procedure in which the organic molecules involved in the synthesis act as both the electron acceptor and electron donor. Thus, in this chemical synthesis the molecule produced does not possess its own entire potential energy. Generally, LAB are used for this fermentation where no or very less amount of heat is required. In batch fermentation procedure the cultures are first made to grow in number of inoculum vessels and then transferred to the fermenter. In general the inoculum volume is 5%–10% of the liquid volume of the fermenter. It is kept at a temperature of 35–45°C and kept at a pH of 6.5. Bacterial fermentation occurs in fed-batch, continuous batch and repeated batch methods. Higher LA concentration is found in fed-batch and batch methods and higher productivity is achieved through continuous cultures. Again continuous cultures could be run for greater periods of time (Ghaffar *et al.*, 2014; Benthin and Villadsen, 1995). Advantages and disadvantages of this fermentative process of LA synthesis is given in Table 1.

Apart from bacteria various other microorganisms can produce lactic acid. The fungus *rhizopus sp.* synthesizes L-(+)-LA at lower yield from starch when compared to LAB. In this case if airlift bioreactor is used 85% of the yield under optimal conditions could be achieved. In this case of fungal mycelia hinder lactic acid production as they increase the medium's viscosity. Thus, lactic acid bacteria which have complex nutrient requirements are used mainly industrially for fermentation processes. Again, product recovery after fermentation is an important step which is done through separation and purification of LA from the broth. For this purpose various methods have been studied including ion exchange, membrane technology, reactive extrusion electro-dialysis, distillation etc (Ghaffar *et al.*, 2014).

Microorganisms Involved in Fermentative Synthesis of Lactic Acid

As discussed earlier, gram positive Lactic acid bacteria (LAB) are used for fermentation of LA. These bacteria are non-spore forming cocci and rods and non-motile. They do not possess cytochromes and porphyrins as a result of which they do not generate ATP.

Table 1 Comparison of advantages and disadvantages of fermentation processes

Fermentation mode	Advantages	Disadvantages
Batch fermentation	Simple operation High product concentration Reduced risk of contamination	Low productivity Substrate and/or end product inhibition
Fed-batch fermentation	Overcome substrate inhibition problem High product concentration	End product inhibition Difficult to conduct optimal design
Repeated fermentation	Time saving process	Requirement of special devices (e.g., hollow fiber module) or special connection lines used for cell concentration
Continuous fermentation	Labour-saving Omission of seed preparation time High growth rates Short main culture High productivity Control growth rates Less frequency shut down process	Incomplete utilization of carbon source

Fig. 1 Metabolic pathways for LA synthesis by LAB. Reproduced with permission from Abdel-Rahman, M.A., Tashiro, Y., Sonomoto, K., 2013. Recent advances in lactic acid production by microbial fermentation processes. *Biotechnology Advances* 31, 877–902.

Thus they grow under anaerobic condition and do not require oxygen for survival but they are facultative anaerobes and are can grow when oxygen is present. These aero tolerant anaerobes are thus protected from the harmful effects of oxygen by-products like hydrogen peroxidase. They also have the ability to ferment hexose to lactic acid which many organisms do not have (Ghaffar *et al.*, 2014). A schematic representation of the metabolic pathways used by LAB in LA synthesis is given in Fig. 1.

Lactic acid bacteria present in the genera of *Lactobacillus*, *Enterococcus*, *Leuconostoc*, *Lactococcus*, *Carnobacterium* etc., ferment carbohydrates through homo, hetero and mixed fermentation pathways to produce LA but homofermentative pathways gives less by products such as formic acid, acetic acid etc., and better yield of LA. However few LA bacteria such as *L. helveticus*, *L. amylophilus*, *L. delbrueckii* and *L. bulgaricus* can produces optically pure L-(+)-LA (Yun *et al.*, 2003).

A comparative account of homo and hetero fermentative LAB is given in Table 2.

These microorganisms have the ability to use cheap raw materials for fermentation and require very little amount of nitrogenous nutrients and have the capability to produce high amount of stereo specific LA under optimal conditions of low pH and high temperature. In this process they produce little amounts of cell mass generating low amount of by products which are industrially desirable. The filamentous fungi *rhizopus sp.* also produce lactic acid.

R. oryzae and *R. arrhizus* directly converts starch into L-(+)-LA owing to their amylolytic activity. These fungi have drawn great interest industrially as their immobilization property had resulted in better yield of the desired products. Nowadays, genetic engineering have also been employed to produce LA. For example *Saccharomyces cerevisiae* have low pH resistance compared to LA bacteria. Thus on experimental basis genetically engineered yeast have been preferred. Again, mixed culture of *Lactobacillus brevis* and *Lactobacillus pentosus* were used to synthesize LA from wheat straw hemicelluloses. *Enterococcus faecalis* RKY1 have also been used to produce LA from sugars. *Escherichia coli* were also used for the generation L-lactate and D-lactate. The strain JP203 was reported as the strain of *E. coli* for good production of D-lactate. This strain also possessed various antibiotic resistant genes (eg., TET and KAN). Repeated batch fermentation process also produced LA from *Enterococcus faecium*. A *Bacillus sp.* strain was also reported to produce L-(+)-LA. This strain possessed thermo-philic properties and optically pure L-(+)-LA can be formed from this strain (Okano *et al.*, 2009).

The synthesized stereocomplex PLA is made of both poly D-(−)-LA and poly L-(+)-LA and has high thermal stability with a melting point of 230°C. This is 50°C higher than the single polymers individually. Thus, this has resulted in the synthesis of pure D-(−)-LA. It has been reported that through the construction of *Lactobacillus plantarum* which is L-lactate dehydrogenase gene (*ldhL1*)-deficient through plasmid insertion pure D-(−)-LA could be synthesized from corn starch encoding *Streptococcus bovis* 148-amyase (AmyA). A high yield of optical purity of about 99.6% was achieved (Mazumdar *et al.*, 2010).

Table 2 Comparative account of homo and heterofermentative bacteria

Characterization	Homofermentative LAB	Heterofermentative LAB
Products	Lactic acid	Lactic acid, ethanol, diacetyl, formate, acetoin or acetic acid and carbon dioxide
Metabolic pathways	Hexose: Embden-Meyerhof pathway Pentose: Pentose phosphate pathway	Hexose: Phosphogluconate and phosphoketolase pathway Pentose: Phosphoketolase pathway
Theoretical yield of lactic acid to sugars	Hexose: 1.0 g/g (2.0 mol/mol) Pentose: 1.0 g/g (1.67 mol/mol)	Hexose: 0.5 g/g (1.0 mol/mol) Pentose: 0.6 g/g (1.0 mol/mol)
Genera	<i>Lactococcus</i> , <i>Streptococcus</i> , <i>Pediococcus</i> , <i>Enterococcus</i> , some <i>Lactobacillus</i> .	<i>Leuconostoc</i> , <i>Oenococcus</i> , some <i>Lactobacillus</i> species.
Availability for commercial lactic acid production	Available due to high selectivity	Not available due to high by-product formation

Note: Reproduced with permission from Abdel-Rahman, M.A., Tashiro, Y., Sonomoto, K., 2013. Recent advances in lactic acid production by microbial fermentation processes. *Biotechnology Advances* 31, 877–902.

Again, genetic engineering in *Escherichia coli* both the microanaerobic and aerobic conditions has achieved a conversion of D-(–)-LA from glycerol (a cheap, easily available source). This was achieved by over expressing pathways for this conversion and consequently blocking of those pathways leading to the synthesis of by-products. In this homo fermentative route overexpression of genes encoding the glycolytic intermediates (GldA-DHAK and GlpK-GlpD and pathways) alongwith that of the synthesis of D-lactate from pyruvate (D-lactate dehydrogenase) was done. Again the for the synthesis of acetate, ethanol and succinate was reduced by engineering those pathways (Mazumdar *et al.*, 2010).

Synthesis of Optically Pure Lactic Acid From Various Renewable Resources

Agricultural wastes or crop residues is an important renewable source. Globally every year approximately 3.5 billion tons of wastes from agriculture are produced. Carbohydrate feedstocks requirement are costly and availability lacks abundance. However, the agro industrial wastes thus produced are rich in carbohydrate sources. However, they are not utilized owing to poor protein content and are also not digestible. Conventionally, the carbon source for LA production has been sucrose, lactose, glucose or molasses, starchy materials (carrot, barley, tapioca, potato), whey, sugarcane bagasse, cassava bagasse etc. The raw material for substrate for LA synthesis is very important. Purified sugars are very expensive. Different agro wastes are more economically viable alternatives. Molasses are often exploited for this purpose. Again, starchy materials are also often used. Agricultural by products like corn starch, cassava starch also can be used. Lignocellulosic materials like hemicellulose hydrolyzates, corn cob, Jerusalem artichokes, corn stalks, wheat bran, beet molasses, sweet sorghum, rye flour, sugarcane press mud, cellulose, carrot processing wastes, molasses spent ash, carrot waste hydrolyzates are also being reported to be sources for LA production (Hofvendahl and Hahn-Hägerdal, 2000; John *et al.*, 2007).

A list of renewable resources which are used for LA production and the microorganisms involved along with the processes is given in Table 3.

As it is well known that LAB does not have amylolytic and cellulolytic enzymes, thus hydrolysis of cellulosic and starchy wastes are required. Enzymatic, steam treatment or acid hydrolysis or by lignocellulosic enzymes are preferred for pre treating the raw materials.

Woody materials are mechanically broken down and bisulfates are used to release the carbohydrates and sugars. This sulphite filtrate could be then used by LAB (John *et al.*, 2007). Acid or enzyme hydrolysed starchy wastes have also been reported. Prior to hydrolysis these materials are often gelatinized. Enzymes like glucoamylase are used for saccharification and alpha amylase for liquefaction. However of all the treatments done on starchy and lignocellulosic materials acid hydrolysis is found to be more economical and less energy is consumed when compared with enzyme hydrolysis. Hemicellulose and cellulose are often hydrolysed with 72% sulphuric acid. This is then further diluted to extract its sugars. Sometimes co- immobilization with starch degrading enzymes of starch-degrading and LAB are also done to get simultaneous sugar generation and saccharification (John *et al.*, 2007). Waste materials are also used for LA generation. The by products from cheese industry whey is often used. Mussel processing wastes from industries also used (John *et al.*, 2007). Li *et al.* (2015) had reported the use of food waste for production of optically pure L-(+)-LA. Again, excessive sludge have been used for open fermentative synthesis of L-(+)-LA by thermophilic bacteria (Ma *et al.*, 2014). Neu *et al.* (2016) had reported the use of coffee mucilage by *Bacillus* sp. for synthesis of optically pure LA.

Applications of Lactic Acid (LA) in Various Industries

The applications of Lactic acid (LA) accounts for about 85% of its usage in food industrial applications and the rest of its production is used in other industries. As mentioned earlier, LA has found its use as an acidulant and preservative in industries (food and beverages) for several years. Chemicals from lactic acid such as calcium lactate and sodium lactate is known to be used

for conditioning and emulsifying purposes. LA is used in food for flavouring purposes, as acidulant and also as for pH buffering. Presence of LA in food inhibits bacterial spoilage in many processed foods and beverages (Datta et al., 1995).

LA and its salts also acts as disinfectants in packaging industry for storing of fish, poultry etc. This is mainly done to reduce spoilage by *Clostridium botulinum* (Datta et al., 1995). It is used extensively in bakery products for emulsifying and conditioning purposes. Cosmetic industry also uses this natural ingredient in creams used for skincare purposes like acne removal (Datta et al., 1995; Wee et al., 2006). Pharmaceutical industry also used it in various topical creams and lotions (Wee et al., 2006). As, mentioned before it is now been used extensively for biopolymer synthesis which have a wide variety of applicability ranging from commodity products to medical prostheses (John et al., 2007). The biopolymer PLA synthesized from LA mainly by condensation polymerization can be degraded biotically by simple hydrolysis of the ester bonds of the molecules (Vijayakumar et al., 2008). Thus synthesis and use of PLA is environmentally sustainable. LA being a green chemical synthesized from renewable resources and PLA is a bioplastic which could be degraded effectively after its use biologically, makes it a product which will reduce GHGs and carbon footprint of this planet. In spite of its various application potential and environmental benefits, the production of PLA is considerably lower than the plastics produced from non-renewable resources. Various limiting factors ranging from economic factors to procurement of renewable resources have been the limiting factors in its production. However, in recent times these limitations are being made to overcome to increase PLA production fro LA (Åkerberg and Zacchi, 2000; Christensen et al., 2008; Pacheco et al., 2012).

Conclusions

Lactic acid (LA) is known to be an important chemical which is required in various industries like chemical, pharmaceutical etc. However, with the rising concerns of increasing greenhouse gases and more use of bio-products from renewable resources is sought after. Bioplastics is one such developing sector industrially in our recent times. Among the various bioplastics being used poly lactic acid (PLA) is one such plastic which is now being industrially produced. These recent advents in PLA productions have

considerably put the focus on synthesis of LA. LA is generally produced by fermentative route by using microorganisms to get optically pure forms of LA. Genetic engineering coupled with newer substrates is now being sought after for LA production. Conventional use of sugars is now being replaced by renewable resources like agro wastes and lignocellulosic materials. These require various pre-treatments before extraction of the sugars from them to produce the optically pure LA by microorganisms. However, they are a cheap, economical and environmentally friendly source for this purpose. Research is now being focussed in this area to produce LA from renewable cheap resources. The use of this chemical for synthesis of PLA is the current focuses for researchers vying for synthesis of economically viable biopolymers. Since, the use of PLA as mentioned earlier, will result in mitigation of GHGs and reduce carbon footprint of this world it is a widely sought after material in today's time and its process of synthesis from renewable materials is also an important field of study (Drumright *et al.*, 2000; John *et al.*, 2007).

Introduction

India is the second most populated country in the world after China. According to sensuous in 2011 its population was 1.21 billion, and according to United Nations of Organizations its population was 1.32 billion in 2016. It has been studied that India's population will reach around 1.40 billion in 2020 and it will surpass China in population at 2022. Due to this growth in population, improper utilization of natural resources has been increased to such an extent that has put adverse effect on ecological balance and as a result nature has been changed largely. Environment has been polluted, nature has lost its purity, and people became sick and going to lose their immunity power.

Due to the massive growth in population, generation of waste has been raised to a very high level. As a result there is an uncontrolled increase in the number of patients and generation of Hospital Waste, (abbreviated as HW) in India. Hospital waste is generated from Government and Private Hospitals, nursing homes, pathological centers, health checkup centers, veterinary hospitals, medical camps, blood donation camps, and in research laboratories. Generation of Hospital Waste is recorded 1–1.5 kg/day per patient in an average in India. According to Press Information Bureau, (Govt. of India, Ministry of Environment and Forest) 2016, it is known that 0.17 million ton Hospital Waste is generated every year in India. The generation of Hospital Waste is increased in a rapid rate throughout the country and has become a threat and impose a mammoth task to dispose it in proper and scientific manner without affecting the environment and human health. Hospital Waste can cause serious diseases if not managed and disposed properly. The infectious germs, pathogens and chemicals can cause health hazard if one comes in direct contact of it without having adequate precautionary measures. It emits toxic gases into environment if burned or put abundantly in open ground for land filling. So a suitable technology is very much required as soon as possible which can dispose HW without affecting our environment. Plasma being the fourth state of matter can generate temperature about 3000–6000°C and is a reliable and viable technology for safe and complete disposal of HW. It can completely destroy pathogens, infectious molecules and emits neither toxin nor greenhouse gases into atmosphere. The volume reduction of HW is about 99% in plasma arc gasification process and gas produced here is mainly a mixture of H₂ and CO which is known to be Synthetic Natural Gas (Syn gas).

A Burden to Modern Age: Hospital Waste and its Classification

Hospital Waste generated from treatment and health-care activities consists of 85% non-hazardous and 15% hazardous wastes. The hazardous HW is mainly infectious, toxic in nature and sometimes, holding radioactive properties too ([HWO Healthcare Waste, 2018](#)). The amount of hazardous waste material is increased when there is not proper segregation of generated waste in hospitals. As a result when non-hazardous HW is mixed with hazardous HW, the entire waste becomes hazardous. There is a variety in generated Hospital Waste, such as:

Infectious Waste

This consists of pathogens which can cause fatal diseases, blood and other body fluids, culture and research of infected body parts and cells, and waste generated from treatment of infectious patients. Diagnostic samples, bandages, some medical treatment devices are mainly infectious during treatment of chronic disease patients ([HWO Healthcare Waste, 2018](#)).

Pathological Waste

These wastes are mainly tissues, body parts, blood, and other body fluids.

[☆]A. Hazra and S. Das have contributed equal share.

Sharps

Needles, syringes, nail, broken glass, blades, disposable and discarded scalpels, saws etc., are sharp HW which may cause serious injuries and contamination if impinged to body.

Pharmaceutical Waste

These are expired drugs, vaccines etc.

Chemical Waste

It include chemicals discarded after being used for cleaning, disinfection etc. Moreover, chemical waste is generated in research work of tissue culture. Heavy metals used in medical devices and instruments are also became a source of chemical waste (as mercury in a broken thermometer).

Genotoxic Waste

These waste materials are highly hazardous in their nature, these are mainly carcinogenic, mutagenic waste products produced in the treatment of patients suffering from chronic diseases like cancer. e.g., cytotoxic drugs used for the treatment of cancer patient.

Radioactive Waste

These wastes are generated through radioactive diagnostic materials which are used for *in-vitro* analysis like tissue, *in-vivo* imaging studies of organ, tumor analysis etc and their related treatment.

Non-Hazardous Waste

These are general wastes which are less hazardous in nature, kitchen wastes, food grain, papers, plastics, wrapper, fruit peels, vegetables etc are some kinds of non-hazardous waste.

Hospital Waste Generation and Treatment: A Brief Survey in India

In most of the cases, Hospital Waste is dumped in open land or sometimes burnt in dumped yards in many places without taking much concern about environment. People come in contact with such contaminated HW experiences potential health hazard. A very few hospitals have proper infrastructure for waste disposal and monitoring system for management of hospital waste (Nema and Ganeshprasad, 2002).

Hospital waste is treated through Incinerator, Autoclave, Microwave, and Shredder at the waste generation site. As per the reports published by Central Pollution Control Board (CPCB) in 2014 it has been found that Incinerator, Autoclave and Shredder are the common methods used in different hospitals in different states of India (Vide Table 1). The other processes are rare to be used.

Existing Conventional Methods for Hospital Waste Treatment in India's Perspective

Till date, Hospital Waste once collected from hospitals is disposed commonly through Land filling, Autoclave, Microwave, Shredder and Incineration processes in India.

In Autoclave technology water vapor at a very high temperature (superheated) is utilized to sterilize the pathogens, infectious germs and other contaminated medical instruments into a closed chamber. A boiler is used to produce saturated steam, which is surrounded through a steam jacket at the Autoclave chamber. Air being an insulator is removed from Autoclave chamber through air suction process. This process is fruitful for disinfection of hazardous hospital waste but the waste remains in its original position. Surgical instruments can be reutilized after being sterilized by this process but hospital waste is not totally treated here, the volume of HW remains unaltered after the treatment. Besides this, this procedure can never be used for radioactive waste, volatile and semi volatile materials, mercury, and waste produced from chemotherapy. However this process is not that much prospective and henceforth useful towards complete and safe disposal of any kind of hospital wastes (Diaz *et al.*, 2005). For complete disposal of HW incineration process is performed after treatment through Autoclave, it makes the entire procedure more costly and critical (Nema and Ganeshprasad, 2002).

Land filling is a frequently and widely used technology for waste disposal in the world and also in India. Hospital wastes collected from different sources are dumped in open land far away from the locality (in general outskirts of a city). Various bio-degradable and bio-non degradable infectious, hazardous waste materials came in direct contact of the environment and causes environment pollution. The bio degradable waste materials produce NH_3 , CH_4 , and CO_2 like greenhouse gases. It causes harmful

effect on the entire eco system of that area. Bio non degradable waste products remain unaltered at the land. Cattle and human being come in direct contact of it or indirectly get in touch of the contaminated hospital waste consisting infectious pathogens became seriously ill. In one hand this process emits greenhouse gases into the environment and in other hand it causes serious health problems and diseases.

Incineration is another process used for hospital waste disposal in different countries and in different hospitals. Hospital waste is combusted into a closed chamber in presence of oxygen. The temperature is about 700–900°C. Waste materials are put into the closed chamber where through an ignition system it is combusted in presence of oxygen. The problem associated with it is the formation of extremely toxins like dioxin and furan at the final outlet. The temperature is not so high as to remove dioxin and furan completely from the combustion of waste materials (Nema and Ganeshprasad, 2002). Besides this, the final gas outlet consists of CO₂, CO, SO₂, NO₂, NO, CH₄, hydrocarbons, water vapor etc (Rajor *et al.*, 2012; Gidarakos *et al.*, 2009). Produced CO₂, CH₄, SO₂, N₂O act as greenhouse gases and are apparently responsible for global warming (Javied *et al.*, 2008). So at one side incineration can't be a great solution for complete disposal of infectious bio medical waste and at another side it causes greenhouse gas emission to the atmosphere too.

Microwave disinfection process is also used to sterilize microorganisms, pathogens present at hospital waste. By using magnetrons, electromagnetic microwave is generated. Microwave is of very short wavelength and high frequency usually results higher friction and as a consequence sustainable heat is generated inside the microwave chamber. Waste materials put inside the microwave chamber is disinfected at a temperature range of 95–100°C (Diaz *et al.*, 2005). However volume of waste remains same here without having much change at the composition of waste. Microwave disinfection can be used for sterilization of infectious pathogens generated through medical treatment but this process is quite inappropriate towards complete disposal of HW. After the disinfection process through microwave, waste materials are either land filled or put in an incinerator for further treatment and disposal (Nema and Ganeshprasad, 2002).

Shredders are used in different health care facilities to reduce the size of produced hospital wastes. This process is helpful towards transportation of HW and reducing the size of waste, whereas it is not a process of disposal or treatment of HW.

Greenhouse Gas (GHG) Emission and its Effect on Environment

In Earth's atmosphere troposphere lies between the earth-surface and about ~16 km above it where dense air is present. In this region some gaseous molecules are present which can efficiently trap heat reflected from the earth surface. Presence of such gases beyond a certain limit causes an increase in temperature of the earth's atmosphere. The gases responsible for this are greenhouse gas and it causes Global Warming which is of a major concern in today's perspective. Adverse effect of global warming can be seen throughout the year in different parts of the globe.

Global warming and emission of greenhouse gases at the atmosphere have become a severe problem in front of the whole world. Certain steps are required to be adopted to reduce the emission of GHGs, in order to reduce the adverse impact of Global Warming. The GHGs are Carbon dioxide (CO₂), Nitrous Oxide (N₂O), Methane (CH₄), Perfluoro-carbon (PFC), Hydro-fluor-oarbon (HFC), etc. The rate of generation of such greenhouse gases is increased due to rapid industrialization and growth in population which enhances the growth in industrial, automobile, construction sectors etc. The uncontrolled direct emission of GHGs into the atmosphere by different industries, emission of unburned hydrocarbons and emission of GHGs from motor vehicles have made the situation more ridiculous.

Carbon dioxide is the most important greenhouse gas contributing about 70% of the total heat absorption of the atmospheric earth surface. Methane contributes about 20% of heat absorption of the total heat absorbed at the atmosphere.

In the last hundred years (reported from 1905 to 2005) the earth's temperature at the surface has been increased about 0.4–0.8°C, water level at sea has increased about 1–2 mm annually. As a consequence climate has been changed and eco-system has been badly affected. In 1990, developed nations as USA, EU, Russia, Australia, Canada and Japan have together contributed about 66% of total GHG emission in the world, meanwhile in 2000, these countries emission of GHG was 54% when China put a greater contribution for GHG emission (Sharma *et al.*, 2006). In the year of 1994, India's contribution was merely 3% (1228 million tons) in terms of GHG emission in atmosphere in the world in which 63% was CO₂ emission, 33% was CH₄ emission and the rest was N₂O (Sharma *et al.*, 2006; Diaz *et al.*, 2005). CO₂ emission was increased about 4.2% per annum between 1990 and 2000. In this decade GHG emission from industry and waste has been increased at a rate of 21.3% and 7.3% per annum respectively. With this pace the emission of CO₂ is expected to reach about 3000 million tons by 2020. With such increase in GHG emissions the Earth's mean temperature is estimated to raise 1.5–5.5°C by the year 2050 and the sea level may increase 0.2–1.5 m in an average within coming 50–100 years (Roop Ganesh, 2011).

Major GHG, CO₂ can stay about 500 years in the Earth's atmosphere and it contributes about 55% towards Global Warming. In the year 1990 the concentration of CO₂ was 355 ppm which has been increasing at a rate of 1.5 ppm in every year. CH₄ has a potential contribution about 18% towards Global Warming which can stay about 7–10 years in Earth's atmosphere. It traps heat even 25 times more than that of CO₂ which made it a very strong contributor for Global Warming. CFC, another GHG is responsible for depletion of Ozone layer at Stratosphere. It can stay in that atmospheric layer for about 65–100 years and traps heat about 1500–7000 times than that of CO₂. The concentration and accumulation of CFC is increasing at a rate of 0.5% every year (Roop Ganesh, 2011).

GHG Impact in Indian Perspective

It has been reported that in 2007 the emission of CO₂ from India was 1728 million tons, where major contributors were energy sector (contributing about 58%), industry (contributing about 22%), agriculture sector (contributing about 17%), and waste products (contributing about 03%). Between the year 1994 and 2007 the rate of generation of GHG per year has been observed increasing at a rate below 6% in electricity, energy, transport, residential, cement, iron and steel plant, agriculture while an increase about 7.3% in GHG emission have been seen in waste disposal. It is estimated that per capita emission of CO₂ will reach 2.1 ton in 2020 and 3.5 ton in 2030 in India (INCCA, 2010).

China holds the first position for total emission of CO₂ (Fig. 1) in the environment with 4.58 tons per capita emission whereas India being the second most populated country in the world emits 1.18 tons CO₂ per capita. USA, Russia, Germany, Japan emits significantly higher amount of per capita CO₂ than India. (Fig. 2) In terms of total emission of CO₂ China, USA, Russia, Japan, India and Germany play the leading role (Table 2).

Generation of GHGs by HW

Waste materials contribute about 3% towards the emission of greenhouse gases. Hospital waste beholds about 15% in an average of the total waste generated per day in the globe. Keeping pace with the growth in population, number of hospitals, nursing homes, health care centers are increasing day by day and as a result hospital waste generation per day is also increasing with an enormous hike. When generated Bio medical or Hospital wastes are land filled or put burned at open atmosphere greenhouse gases produce and affect a poisonous, deleterious atmosphere which renders environmental cleanliness. Land filling is a common technology for waste disposal in India which causes a serious environmental degradation and bio organic infectious waste materials produce methane gas which is considered a major greenhouse gas. Whereas autoclave, microwave disinfection and shredding procedures require additional disposal methods like incineration which cause additional adverse environmental impact

and make it more polluted. As greenhouse gases are also produced through incineration process it causes harmful effect on our environment and its impact is enormous with respect to global warming.

Results and Discussions

Plasma Driven Arc: A Viable Approach in HW Management and Treatment in India

Plasma is considered as the fourth state of matter, which consists of positively charged ions, electrons and neutral particles, that make a collective behavior but maintaining the whole system electrically neutral (Leal-Quir'os, 2004; Dighe *et al.*, 2001). The

Scheme 1 Schematic diagram of HW disposal plant at CSIR-CMERI. Reproduced from our own developed set up.

temperature of plasma is as high as 5000–10,000°C. Plasma arc is generated in a closed chamber utilizing high velocity high temperature fluid medium and also by generating arc between two terminals of cathode and anode electrodes. Such high temperature is capable enough to destroy pathogens, infectious hazardous molecules, contaminated hospital waste etc. completely. Moreover the advantage of plasma arc treatment is the generation of significantly less amount of toxic products like dioxin and furan which is much below the standard limit of toxic emission in the environment. Waste materials need not get segregated in plasma arc treatment process, organic materials are completely gasified and inorganic materials are turned into non leachable high density vitrified slag. Here the volume reduction of organic materials is about 99% (Nema and Ganeshprasad, 2002). Generated plasma plume is capable to produce and maintain a very high thermal atmosphere inside the plasma reactor which makes the applicability of plasma arc technology towards complete and safe disposal of HW and this phenomenon makes the difference between thermal plasma and other processes available for waste disposal.

A Small Scale Plasma Arc Driven HW Treatment Plant in Remediation of Generated HW: An Attempt Towards HW Mitigation

A mini plant of a few 10 kg/h has been set up at CSIR-CMERI, Durgapur (vide [scheme 1](#)) for disposal of Hospital Waste by utilizing high temperature electric arc plasma. It is completely a new process to treat HW in India. The waste material is fed into plasma cracker unit where three plasma torches are utilized for gasification of waste materials. The plasma torches are made of graphite cathode and tungsten impregnated carbon anode. Superheated water vapor is used as carrier fluid for generation of plasma plume. The plasma cracker unit is designed in such a manner so that plasma electrodes can also be used for plasma arc generation instead of plasma torch. It might be a rare combination of using plasma torch as well as plasma electrode together for plasma arc generation in plasma cracker unit. The waste gets gasified inside the plasma cracker unit in absence of oxygen. Thus produced gas consists of mainly a mixture of CO, H₂ which is synthetic natural gas (Syn gas). From the plasma cracker unit in the next stage the gas mixture is passed through a secondary chamber of incineration where it is combusted in presence of oxygen. Then the produced gas mixture is passed through catalytic converter and redox reactor. Here the higher hydrocarbon present in waste materials, reacting with nickel mesh present at catalytic converter becomes lower hydrocarbon i.e., if CH₄ is present in the gas mixture it becomes CO, CO₂ and H₂. Then gas passes through the redox reactor which comprises of carbon sieves. Here steam present in the gas mixture usually reacts with carbon sieves and produce CO, CO₂, and a little amount of H₂O.

After that the produced gas passes through an ammonia scrubber followed by a water scrubber. The toxic gases as HCl, SO₂ (if present at the gas mixture) are removed by simultaneous treatment from ammonia and water scrubbers. The evolved gas mixture is passed through condenser where the temperature of the gas mixture is lowered down using a water cooling fan. Finally the generated gas mixture is released to the atmosphere through a 30 m height chimney to the open air. The toxin free combusted gas is harmless to open air.

Plasma Arc Generation and Secondary Treatment in HW Plant: A Real Day Solution in Modern Age

Utilizing plasma arc technology for safe disposal of Hospital Waste (HW) is hitherto less explored R & D domain in India. Here not only the HW gets completely destroyed but also the final emissive gas mixture released in air holds lesser extent of greenhouse gases, also non toxic gases. The infectious and hazardous HW is gasified at plasma cracker unit through a star shape three numbers of transferred plasma torches. A newer and greener technology is simultaneously utilized and adopted for generation of plasma arc. Using a rarefied combination of mechanical components like catalytic converter, redox reactor, ammonia scrubber, water scrubber, condenser, secondary chamber, and chimney ~ 30 m are assembled which is an innovative approach for HW treatment. Here secondary chamber is additionally utilized for making sure that there should not be any infectious pathogens; dioxin or furan remains at the exhaust gas mixture. The gas mixture takes residence time of about 3 s to pass through secondary chamber which is of national standard protocols for waste disposal through incinerator. To be in safer side, this particular Secondary Chamber is

placed just after the primary plasma cracking chamber. In continuation catalytic converter and redox reactor are improvised within the system to produce less carbon and high calorific value synthetic natural gas ($\text{CO} + \text{H}_2$) abbreviated as syn gas.

Secondary Chamber Treatment @ Viable Route for Pathogen Destruction

Plasma electrodes and torches are operated in 30–50 V and in 200 Amp DC current supply of main source. Superheated water vapor about temperature 300–400°C, pressure at 4 kg/cm² is used as carrier gas for plasma arc generation at plasma torch. The temperature generated through plasma torch inside the plasma cracker lies in between 3000 and 6000°C which is capable enough to completely destroy the pathogens present in HW. The organic waste materials are gasified and it produces syn gas while the inorganic components (metal, ceramics, glass etc.) are melted and are stored at the bottom of the plasma cracker as a slag material which is recovered in timely basis and furthermore is utilized for producing building construction materials like bricks.

Through electric spark, ignition is performed into the secondary chamber and the temperature inside it varies between 1000°C and 1500°C. If any unburned pathogens remain there at the gas mixture, it will be completely get burned and destroyed in this secondary chamber due to its higher temperature. The hospital waste is no way directly incinerated in this chamber, but the gas mixture produced by plasma arc gasification of HW is incinerated here. So the problem associated with the direct incineration of waste material and emission of greenhouse gases are not laying here. Only the gas mixture gets combusted here. Through this primary plasma arc gasification chamber followed by incineration treatment in secondary chamber it makes sure that HW is completely destroyed.

To make sure of that there is significantly nominal emission of toxic gases from HW plant, a study has been done. Detection of toxins like dioxin and furan concentration requires sophisticated instruments like GC-MS. This cannot be afforded in online system, so the gas mixture is adsorbed primarily in porous materials then is analyzed.

The Gas Collection Procedure for Dioxin and Furan Analysis Form HW Disposal Plant

After plasma treatment of HW, produced gas is further burned inside secondary chamber. After successive burning the gas is lead through a 30 m chimney. The analysis of emitting gas mixture is highly needed from the environmental concern. In analysis, measurement of dioxin and furan contents in emitting gas mixture is very much important. As the adverse toxicity and higher possibility of generation of dioxin and furan lies in waste management plants, the analysis of gas component is having the utmost necessity.

Detection of dioxin and furan concentration requires sophisticated instruments like GC-MS. This cannot be afforded in online system, for which a porous adsorption material is required for encapsulation of the desire gases. In this case, porous resin is used for adsorption purpose. In collection process of gas sample, interventions of other impurities like soot, moisture are prevented with a specially designed sample collection system. In the above diagram (Fig. 3) the soot trapper and the sample collection box work as a suitable system in an integrated manner. Inside the box, gases are forced to be trapped inside the porous material and after saturated adsorption the material is sent for the GC-MS analysis.

In gas collection process, (vide scheme 2) the gas mixture is flown through a shoot trapper where the unwanted shoot particles are trapped. This is done so as the shoot particles may not interfere in collection of desired gas mixture through sampling box. In sampling box the gas mixture is passed through a condenser where the temperature is getting lowered down by introduction of cold water inside the condenser chamber. Through this condensation method the moisture content in gas mixture gets sorted and is being collected differently in the sampling box. Then the gas is passed through a sampling chamber, where the gas is driven through porous resin and been adsorbed in porous resin. Finally from the sampling box, it is flown through a flow meter where the flow velocity of gas is measured. The gas adsorbed in porous resin is then tested in GC-MS.

Fig. 3 Flow diagram of gas collection process. Figure is constructed based on our own working process.

Scheme 2 Schematic diagram of gas collection process from chimney. Fully schematic, not reproduced from anywhere.

Table 4 Gas analysis report after being treated in Secondary Chamber

Sl. No.	Parameter	Unit of measurement	Results
1.	Carbon Monoxide(CO)	mg/m ³	<1.0
2.	Carbon dioxide (CO ₂)	%	9.2
3.	Sulphur Dioxide(SO ₂)	mg/m ³	2.0
4.	Oxides Of Nitrogen(NO _x)	mg/m ³	53.0
5.	Particulate Matter	mg/Nm ³	29.0
6.	Oxygen (O ₂)	%	11.0

Note: Our own R&D result.

Analysis of Emission of Toxin as Dioxin and Furan after Being Treated in Secondary Chamber

The analysis shows that the total presence of toxins like dioxin and furans are less than 0.01 mg.TEG (**Table 3**) in the produced gas mixture after being treated in plasma cracker unit and then in secondary chamber is below than the national standards set by Central Pollution Control Board. Also the final emission of GHGs holds lesser amount of CO, SO₂, NO_x into atmosphere (**Table 4**). Thus plasma arc driven system is the most viable recently developed HW disposal technology where the treatment plant

emits less toxic gases into atmosphere that makes it a real day solution for disposal of waste and maintain an eco-logical balance of the surrounding.

Conclusion

In summary, disposal of HW, maintaining a green and clean environment is a real challenge all over the world. In India, Central as well as different State Governments has taken several impressive and noteworthy initiatives for cleanliness, safe disposal of waste materials and environment protection. The general public awareness has been roused through campaigns like "Swatch Bharat Mission". Safe handling, safe transportation, and finally safe disposal of hospital waste by several R&D organizations, NGOs and self help group throughout India are taken care keeping in mind of the 2020 vision of waking India to give birth a clean, eco-friendly, and healthy environment for its mankind. In present days out of other noteworthy initiatives for disposal of HW, plasma arc driven technology is perhaps the most reliable and authentic technology keeping it in mind that this technology is viable for drastic volume reduction of generated HWs, lesser extent of toxin and dioxin like gas emission and above all an user-friendly green technology in a viable manner.

Geological Storage of CO₂ to Reduce Greenhouse Gases

Ramesh K Agarwal, Washington University in St. Louis, St. Louis, MO, United States

© 2020 Elsevier Inc. All rights reserved.

Introduction

Modern society consumes tremendous amount of energy. For example, the worldwide energy consumption was 168,519 TWh or 6.07×10^{20} J in 2015 (World Energy Consumption, 2015). Moreover, energy demand in the future will keep on increasing due to the growing population, economy and standards of living. A prediction from US Energy Information Administration (EIA) indicates that by year 2035, worldwide energy consumption will reach approximately 7.8×10^{20} J, a 50% increase from year 2008 (U.S. Energy Information Administration, 2010). Prediction and analysis also suggest that the majority of this energy demand will be met by utilizing the fossil fuels. About 80%–90% of worldwide energy in 2008 was derived from the combustion of fossil fuels. Currently, utilization of fossil fuels provides the most affordable solution for the world's energy demand; however various undesirable byproducts are generated by the combustion process. One of the major by-products of combustion is the greenhouse gas carbon dioxide (CO₂), which has been shown to be directly related to increase in global mean temperature of the surface of the Earth, potentially giving rise to global warming.

Three approaches have been identified by the scientists for mitigating global warming caused by CO₂ emissions from fossil fuel consumption: (1) capture CO₂ from the emission source and permanently sequester it; (2) improve combustion efficiency and employ techniques to convert CO₂ to non-greenhouse products, and (3) switch the energy generation from greenhouse gas producing sources to renewable carbon free sources. Among all these approaches, carbon capture and geological carbon sequestration (GCS) is considered to be most promising in the near term. GCS can provide quick, efficient and economical solution to the excessive anthropogenic carbon emission without drastic change in energy generating sources and technologies (Intergovernmental Panel on Climate Change, 2005).

Various geological structures have been identified for possible deployment of geological carbon sequestration (GCS) – deep saline aquifers, depleted oil/gas reservoirs, un-mineable coal seams, etc. According to the estimates by the US Energy Information Administration (EIA), deep saline aquifers appear to be the most viable candidates since their storage potential is sufficiently large to achieve the required carbon emission reduction target. Geological surveys and pilot studies of Saline Aquifer Geological Carbon Sequestration (SAGCS) can be dated back to 1990s'. Although some promising results have been obtained, this technology is still not considered mature for large scale industrial deployment since many uncertainties about sequestration efficiency and safety still exist. Concisely, SAGCS is an activity with coupled physical and chemical phenomena, such as hydrostatics, fluid dynamics, geological physics and chemical reactions, which occur over many spatial (from nano to macro) and temporal scales (from nano to macro). Therefore, the experimental study of SAGCS at all scales is simply not feasible and is likely to be very costly. However, numerical simulations can be performed at all scales to study SAGCS. Thus, numerical simulation approach offers a promising avenue for the purpose of quick screening, evaluation, and prediction of strategies for GCS.

Over the last decade, numerical simulation programs have been developed in US, Europe and Japan to determine a priori CO₂ storage capacity of a saline aquifer and to provide risk assessment with reasonable confidence before the actual deployment of CO₂ sequestration can proceed with enormous investment. In US, TOUGH2 (Transport of Unsaturated Groundwater and Heat, version 2.0) numerical simulator has been widely used for such purpose. Numerical simulations using TOUGH2 can help in determining the influence of uncertainties in SAGCS practice such as the hydrogeological properties of the aquifer (Pruess, 1999; Pruess *et al.*, 2011). Additionally, they can provide insights into the reservoir performance and the flow transport phenomena. More advanced versions of TOUGH2 include TOUGHREACT (Xu *et al.*, 2004) and TOUGH + codes (Moridis *et al.*, 2008).

The objective of this chapter is to provide information and insights into the flow transport in SAGCS for improved understanding and estimation of reservoir performance, including its pressure response, leakage risk, and in situ CO₂ footprint by providing two examples of large scale industrial projects. It is hoped that this review of modeling and simulation studies related SAGCS should be beneficial for better understanding of in situ CO₂ migration and trapping mechanisms, as well as the CO₂ mitigation and commercialization potential of SAGCS.

Basic Ideas and Fluid Dynamics Behind GCS

The earth crust consists of layers of geological formations, which are generally quite distinct from each other in hydrogeological properties and in situ conditions. A geological reservoir forms when one layer of formation with large void space is bounded by other formations with less void space. Existing oil and gas reservoirs can all be characterized in this manner. Analogously, with proper hydrogeological properties and in situ conditions, highly concentrated CO₂ captured from large stationary emission sources can be injected into such formation and is likely to be confined underground for thousands of years without major concerns of its leakage. Following such idea, GCS process can be described as follows. CO₂ is first separated at the emission source (the process is known as carbon capture), then compressed and transported to the storage site, and finally injected into the selected

Fig. 1 Schematic of carbon capture and sequestration. Reproduced from National Mining Association, 2015. Fact Sheet on Carbon Capture and Storage. (online) Available at: http://www.nma.org/pdf/fact_sheets/ccs.pdf (accessed 15.08.18).

geological formation for permanent sequestration (the process is known as GCS). **Fig. 1** shows the schematic of GCS process (National Mining Association, 2015). Since the CO₂ capture process and devices are generally complex and highly energy consuming, large stationary CO₂ sources are more suitable for deployment of carbon capture technology and sequestration. A good example of a large stationary carbon source is the large coal-fired power plant.

In GCS, four major trapping mechanisms can be identified which are responsible for confining the injected CO₂ in the sequestration site for large time period of thousands of years (Herzog and Golomb, 2004; Johnson *et al.*, 2004). These trapping mechanisms are described below.

- **Structural and stratigraphic trapping.** The geological formations selected for GCS can be considered as a CO₂-tight geological container underground. Therefore, three structures recognized as upper, lower and lateral confining formations must be present to keep the in-situ CO₂ confined within the sequestration formation. The lateral extent of the sequestration formation is generally very large. Due to buoyancy, anticline formed by topography of the upper confining formation is usually the preferred location for structural trapping. Structural trapping occurs very quickly and is responsible for trapping the majority of in situ CO₂ during the early stage of GCS project when most of the in-situ CO₂ is still mobile. However, it provides least amount of security in sequestration due to the relatively high risk of leakage. An illustration of structural trapping is shown in **Fig. 2** (upper-left).
- **Residual trapping.** The void space of the storage formation is originally filled with formation fluid, such as impotable saline water in deep saline formations. When CO₂ is injected into the formation, pressure driven Darcy flow will occur and the original fluid in the formation is displaced as in situ CO₂ moves through the porous formation. As CO₂ continues to migrate away from the injection well, some of it is left behind in the form of disconnected droplets in the pore spaces, which is called residually trapped CO₂. These isolated residual droplets remain immobile due to the capillary pressure. Residual trapping therefore provides better immobility in sequestration; however, the amount of residually trapped CO₂ is relatively small and furthermore the development of faults/cracks in the formation may cause its release. An illustration of residual trapping is shown in **Fig. 2** (upper-right).
- **Solubility trapping.** The injected CO₂ can be considered as the solute and the original formation fluid (usually brine) as the solvent. In situ CO₂ gradually dissolves into the formation fluid at the contact surface. Because the formation fluid with dissolved CO₂ is slightly denser than the surrounding fluid, it tends to sink to the bottom of the formation over time, trapping

Fig. 2 Four major trapping mechanisms of GCS. Reproduced from National Mining Association, 2015. Fact Sheet on Carbon Capture and Storage. (online) Available at: http://www.nma.org/pdf/fact_sheets/ccs.pdf (accessed 15.08.18).

the dissolved CO₂ more securely. However, the dissolution of CO₂ into brine water tends to be a process that occurs very slowly. An illustration of solubility trapping is shown in Fig. 2 (lower-left).

- **Mineral trapping.** The dissolved CO₂ results in weak carbonic acid formation fluid. Over a long period (hundreds to millions of years), however, the carbonic acid fluid may react with minerals in the formation matrix and form carbonate minerals as precipitates. Once such carbonate minerals are formed, the in situ CO₂ can be considered to be sequestered with ultimate security. An illustration of mineral trapping is shown in Fig. 2 (lower-right).

Thus, the ultimate sequestration of captured CO₂ is expected to be complete after a considerably long period of time. Each of the above four trapping mechanisms dominates during different time periods in the complete GCS process, therefore having a different level of sequestration security in various time periods. Fig. 3 illustrates the dominant timeframes, storage contribution, storage security, and governing principles of various trapping mechanisms (Intergovernmental Panel on Climate Change, 2005).

The sequestered CO₂ needs to be isolated from the drinking water supply and must be prevented from releasing into the atmosphere, by effectively utilizing all four trapping mechanisms. Monitoring is needed throughout the life cycle of the GCS process to ensure sequestration security. When conducting research on GCS, the time scale of interest as well as the spatial scale of interest must be determined prior to carrying out any substantial work, since different physical principles govern the fate of in situ CO₂ for different trapping mechanisms.

Saline Aquifer Geological Carbon Sequestration (SAGCS)

Studies on GCS have suggested that various geological structures can serve as potential CO₂ storage sites. The major geological carbon sinks include the following structures: (1) conventional hydrocarbon reservoirs, (2) un-minable coal seams, (3) matured oil/gas reservoirs, and (4) deep saline formations. Among these candidates, US DOE has determined that the carbon sequestration in saline aquifers has the greatest potential considering the following facts.

- Concentrated locations of major sources of CO₂ (such as power plants) are close to the existing saline aquifers in US.
- Geological survey has confirmed vast geological distribution of deep saline formations possibly suitable for GCS in US and Canada.
- Preliminary estimates have suggested large storage capacity of the existing deep saline formations. The US DOE estimates an aggregate storage capacity of approximately 919–3378 billion metric tons of CO₂ for SAGCS in US, which accounts for 80%–90% of US overall GCS potential (U.S. Department of Energy, Office of Fossil Energy, 2008).
- Since most of the saline formations are located deep underground, i.e., at least 800 m below the sea level, they provide great potential for secured long-term sequestration.
- Many surveys, research projects and commercial projects have already been conducted for SAGCS, making it attractive for further research and technical contributions.

Numerical Simulations of SAGCS

The large spatial extent of the order of kilometers and time duration of the order of centuries for CO₂ plume migration after injection makes the study of SAGCS very difficult at these large spatial and temporal macro-scales by using the laboratory scale experiments which can be conducted only on relatively small spatial and temporal scales varying from nanometers to a few meters and from nanoseconds to a few days/months. Conducting field tests in large scale formations before the actual deployment takes place can be very expensive. However numerical simulations using computation fluid dynamics (CFD) technology can be employed at industrial scale to determine the fate of injected CO₂ in a reservoir. With the development over four decades, CFD technology has now become mature and has been widely and successfully applied to various engineering problems. With the proper modeling of the storage formation and ground water transportation, CFD is capable of providing accurate enough analysis for quick estimation of reservoir performance at considerably lower cost. The governing equations of mass/energy transportation and numerical representations of the formation properties have been well explained in the TOUGH2 User's Guide (Pruess *et al.*, 2011) and are not presented here for the sake of brevity. Another important benefit of numerical simulations is that one can investigate the effect of various injection parameters such as injection rate, injection duration, and injection well orientation and displacement on CO₂ storage efficiency and plume migration in a given reservoir.

In a complex simulation like that of SAGCS, it is impractical to integrate all geophysical and geochemical effects into one single model while retaining acceptable computational efficiency. Therefore, careful examination of physical phenomenon of interest in SAGCS is essential to determine simplifications in modeling of features of interest. Celia and Nordbotten describe various spatial and temporal scales in SAGCS and the associated processes and their features as shown in Figs. 4 and 5 (Celia and Nordbotten, 2001, 2009).

Additional advantage of numerical simulations is that they make it possible to perform optimization studies of various injection parameters for achieving the highest possible storage efficiency and minimum plume migration.

Some Examples of Simulations of GCS in Large Scale Saline Aquifers

The accurate large-scale simulations of existing (completed/continuing) SAGCS projects for identified known aquifers are crucial to create confidence in the future deployment of SAGCS projects. Although detailed history-matching simulations of existing SAGCS projects are challenging due to various uncertainties, e.g., in the reservoir topography and hydrogeology, the simulations can still provide informative insights in several aspects of SAGCS, such as the variance in multiphase flow properties, integrity of the geological seals, and the mechanism of CO₂ trapping. Such insights are essential for better understanding of the nature of SAGCS and its best practices for deployment. Detailed history-matching simulations have always been an important part in the SAGCS research activity. In the following two sections "SAGCS Simulation for Mt. Simon Formation" and "SAGCS Simulation for Utsira Formation", SAGCS simulations for two large scale industrial GCS projects are provided (Zhang, 2013)

SAGCS Simulation for Mt. Simon Formation

Located at Illinois basin, Mt. Simon sandstone formation is a huge saline aquifer that covers most of Illinois, southwestern Indiana, southern Ohio, and western Kentucky. The estimated storage capacity of Mt. Simon formation ranges from 27,000 to 109,000 million tons of CO₂ (Leetaru *et al.*, 2008; Barnes *et al.*, 2009). Midwest Geological Sequestration Consortium (MGSC) is the regional consortium conducting studies of the possibility of large scale GCS throughout the Illinois basin (Midwest Regional Carbon Sequestration Partnership, 2011). Decatur GCS Project and FutureGen 2.0 Project are two most well-known SAGCS projects being currently carried out at Mt. Simon formation.

The depth of Mt. Simon formation varies significantly throughout its coverage (Leetaru *et al.*, 2008; Barnes *et al.*, 2009). In the southern part, it reaches as deep as 4300 m below the mean sea level (MSL); while it increases to 80 m below the MSL in the north.

Consequently, a south-north geological slope of approximately 8 m/km has been estimated. The thickness of Mt. Simon formation also changes significantly. A maximum thickness of 800 m in the north has been measured while it diminishes to zero in the further south. Furthermore, the variance in topography and analysis of rock samples has suggested strong anisotropy in the formation's hydrogeological properties, with porosity ranging from 0.062 to 0.2 and permeability ranging from 5 mDarcy to 1000 mDarcy. Low permeable Eau Claire shale which sits above the Mt. Simon formation serves as the caprock. Except for some small regions near Mississippi river, Eau Claire shale is considerably thick (more than 90 m) throughout most of the Illinois basin. The security of SAGCS over Mt. Simon formation is therefore assured by the continuous coverage of Eau Claire shale. Precambrian granite formation stretches beneath Mt. Simon saline aquifer.

Recent geological survey has suggested an area in the center of the Mt. Simon formation to be the core injection area – an area in which future storage sites are likely to be located. This core injection area is indicated as the area compressed by white boundary in [Fig. 6](#), along with the elevation information of Mt. Simon formation. As can be seen from [Fig. 6](#), both ADM project and FutureGen 2.0 project are located in the core injection area.

Mt. Simon sandstone is a typical stratified saline formation. According to the geological survey, strong anisotropy in porosity, permeability, and capillary pressure exists through the entire depth of the formation. Based on variance of porosity, Mt. Simon formation can be distinguished as four subunits, namely an upper unit with sandstone and shale tidally influenced and deposited, a middle unit with relatively clean sandstone, an Arkosic unit with highly porous and permeable sandstone, and a lower unit with decreased porosity and permeability. The high porosity and permeability of Arkosic unit makes it an ideal candidate for the injection to take place. When modeling, these four subunits of Mt. Simon are further divided into 24 layers, each of which has a layer-averaged porosity and permeability value ([Leetaru et al., 2008](#); [Zhou et al., 2010](#)). With the consideration of data availability, a candidate site for future sequestration project, the Weaber-Horn #1 well (WH #1 well shown as the red dot in [Fig. 6](#)), has been chosen in the simulation study. The detailed well log of WH #1 is summarized in [Table 1](#) ([Midwest Regional Carbon Sequestration Partnership, 2011](#)). It is important to model the anisotropy of hydrogeological properties as accurately as possible to capture its effect on in situ CO₂ transport. It should be noted that the lower unit of Mt. Simon formation is not considered in the modeling due to its absence near WH #1 well. Both Eau Claire shale and Precambrian granite are modeled as impermeable formations.

Fig. 6 Core injection area and elevation of Mt. Simon Sandstone.

Table 1 Porosity, permeability, and characteristic capillary pressure of the 24 layers of Mt. Simon at injection site WH #1

Sub-unit	Sub-layer	Layer depth (m)	Mean porosity	Mean permeability (mDarcy)	Characteristic capillary pressure (bar)
Upper Unit	1	2140–2150	0.061	5	0.37
	2	2150–2182	0.109	300	0.06
	3	2182–2197	0.074	10	0.28
	4	2197–2203	0.083	3.6	0.4875
	5	2203–2230	0.195	110	0.1
	6	2230–2232	0.071	1.1	0.8
	7	2232–2280	0.13	210	0.083
Middle Unit	8	2280–2322	0.083	5.4	0.4125
	9	2322–2331	0.24	150	0.0875
	10	2331–2340	0.088	8	0.35
	11	2340–2350	0.156	800	0.095
	12	2350–2370	0.25	80	0.125
	13	2370–2378	0.163	900	0.095

	19	2424–2430	0.161	850	0.05
	20	2430–2462	0.128	60	0.15
Arkosic Unit	21	2462–2500	0.202	1000	0.05
	22	2500–2502	0.14	190	0.09
	23	2502–2537	0.151	1000	0.04

Note: Midwest Regional Carbon Sequestration Partnership, 2011. CO₂ Injection Test in the Cambrian-Age Mt. Simon Formation, Final Report. 'Battelle, Columbus, OH'.

A cylindrical model of Mt. Simon formation is constructed. For thermal condition the model uses calculated values with a thermal gradient of 9.2°C/km. The reservoir pressure is assumed to be hydrostatic pressure with a gradient of about 10.8 MPa/km from the ground surface. Salinity is assumed to increase with the depth, starting from 235 mg/L at 450 m below ground surface with a gradient of 12.8 mg/L per meter in depth. A north-south geological slope of 8 m/km is also considered in the modeling. "No-flux" boundary condition is applied at top and bottom of the model, representing the impermeable upper and lower bounding formations. "Fixed-state" boundary condition is imposed at the lateral boundary to represent an essentially "open" reservoir. The permeability and porosity of the 24 sublayers can be noted in Fig. 7.

Fig. 7 (a) Permeability, (b) porosity and computational mesh of the 24 sub-layers of the Mt1 well.

Fig. 8 Saturation of gaseous CO₂ at (a) 5th, (b) 25th, and (c) 50th year of injection.

Due to the relatively high porosity and permeability, CO₂ injection is assigned at the bottom of Arkosic unit (bottom three sub-layers). The injection rate is assigned to be 5 million tons per year and injection lasts for 50 years. CO₂ footprint at 5th year, 25th year, and 50th year since the beginning of injection is examined. **Fig. 8** shows the saturation of gaseous CO₂ at (a) 5th (b) 25th and (c) 50th year of injection.

As can be seen in **Fig. 8**, CO₂ plume evolves with a complex spatial pattern during the 50 years of injection. Within the Arkosic unit where the injector is located, extensive lateral migration with relatively higher concentration of gaseous CO₂ can be observed. In the overlying sub-layers, however, strong secondary sealing effect that retards the vertical migration of gaseous CO₂ is observed as the pyramid-shaped subplume. Detailed analysis of secondary sealing effect is made as follows. As shown in **Fig. 8**, the injected CO₂ migrates laterally away from the injector within the highly permeable Arkosic unit in the first 5 years since the beginning of injection. Simultaneously, buoyancy also leads to upward movement of CO₂ until it encounters the immediately overlying low permeability sublayer (sublayer #20). The low permeability of sublayer #20 directly results into higher capillary pressure experienced by mobile CO₂, and thus stronger vertical pressure gradient is required for mobile CO₂ to penetrate sublayer #20. When the capillary pressure is greater than the phase pressure of CO₂, sublayer #20 appears to be “impermeable” to the underlying CO₂ plume. Consequently, gaseous CO₂ accumulates under this layer and continues spreading out laterally, finally reaching a maximum extent of approximately 3000 m. Meanwhile, the increased CO₂ column under sublayer #20 brings up its phase pressure. Once the phase pressure of CO₂ exceeds the entry pressure of the sublayer #20, mobile CO₂ breaks the capillary barrier of its overlying layer and starts to penetrate it. Such accumulation-penetration-breakthrough behavior of gaseous CO₂ occurs each time the upward migrating CO₂ encounters an overlying sublayer with lower permeability. Because the high capillary entry pressure of the overlying layer temporarily prevents CO₂ migrating upwards, such phenomenon is identified as secondary sealing effect. As can be seen from **Fig. 8**, secondary sealing effect is a very effective means to retard the upward migration of in situ CO₂. Its contribution makes gaseous CO₂ barely reach the Eau Clair shale even after 50 years of injection.

SAGCS Simulation for Utsira Formation

The Sleipner project near the Norwegian coast at North Sea is probably the most prestigious, important and successful SAGCS demonstration so far. It has the most complete topographic description, industrial-scale injection amount, and long-term monitoring data. Nevertheless, great uncertainties still exist for accurate reservoir-scale simulation of the Sleipner SAGCS project. Simulation studies of this project can provide helpful insights in understanding the transport behavior of in situ CO₂ and the reservoir performance.

Starting from 1996, the Sleipner field in the North Sea has been the host of the world’s first commercial SAGCS project. CO₂ is captured from the gas mixture produced from a nearby deeper natural gas reservoir. Until today, approximately 1 million tons of supercritical CO₂ has been sequestered annually. Utsira saline aquifer is the target formation for permanent carbon sequestration for the Sleipner SAGCS project. Utsira formation is located at a depth of 800–1100 m from the seabed with thickness of about

Fig. 9 Seismic image of Utsira formation after 9-years of injection, S–N cross-section. Reproduced from Leetaru, H., Frailey, S., Damico, J., *et al.*, 2008. Developing a geological model for the phase III (ADM) saline sequestration validation site. In: Proceedings of the 7th Annual Conference on Carbon Capture and Sequestration.

Fig. 10 Amplitude maps of Layer 9 from 1999 to 2008. Reproduced from Singh, V., Cavanagh, A., Hansen, H., *et al.*, 2010. Reservoir modeling of CO₂ plume behavior calibrated against monitoring data from Sleipner, Norway. In: Proceedings of the SPE Annual Technical Conference and Exhibition. Society of Petroleum Engineers.

200–250 m. The injection site is located at the southern portion of Utsira formation. A 250–330 m thick shale layer known as the Nordland Formation serves as the caprock, and core testing has suggested its potential of bearing CO₂ column of at least 100 m but perhaps up to 400 m (depending on the in situ conditions). It is estimated that Utsira formation has permeability of about 1 Darcy – 8 Darcy, porosity of about 0.35–0.4, and temperature of about 34–37°C. It is also estimated that the reservoir bears hydrostatic pressure from its overburden formations. Similar to Mt. Simon formation, Utsira formation is also highly stratified, consisting of sublayers with high-permeability sandstone and low-permeability shale. Therefore, it is expected that secondary sealing effect will occur. Fig. 9 shows a 2-D seismic image taken in 2008 revealing CO₂ plume in Utsira formation. Multiple layers can be distinctly identified from the seismic image.

Here we describe a model of Utsira formation which only considers a total area of 48 km² of detailed topmost sandstone layer (marked as Layer #9 in Fig. 9). Layer #9 is of particular interest regarding the safety of this sequestration project, as it is the layer within which highest concentration of gaseous CO₂ exists and most significant plume migration occurs. Detailed topography of Layer #9 makes it a complicated 3D model as shown in Fig. 10. The 3D Layer #9 model is considered to investigate the effect of actual topography on in situ CO₂ migration, while avoiding intensive computational effort associated with full 3D modeling and simulation of the entire Utsira formation. Seismic survey has shown striking growth of CO₂ accumulation in Layer #9 between 1999 and 2006 as shown in Fig. 10 (Singh *et al.*, 2010).

The black dot in Fig. 10 marks the location of the injection well, which is roughly 200 m under Layer #9. Two distinct local CO₂ accumulations appeared after about three years of injection (recall that injection began in 1996), indicating CO₂ began to accumulate under the caprock. However, CO₂ migration in Layer #9 was not symmetric due to the topography of the caprock. The northward migration of initially impacted CO₂, seen as the “body” of the plume in Fig. 10, implies a local topographic dome; a prominent north-tending migration, seen as the “finger” of the plume in Fig. 10. It implies the spill of local structurally trapped CO₂ along a north-tending topographic ridge. CO₂ migration along the north-tending ridge is rather fast at about 1 m/day between 2001 and 2004 (Chadwick and Noy, 2010).

Fig. 11 3D overview and plan-view of the 3D Layer 9 model of Utsira indicating feeder locations, black dot – main feeder, cyan square – secondary feeder.

Table 2 Hydrogeological properties of the Utsira Layer #9 model

Temperature	33°C
Pressure	8.6 MPa
Total Utsira formation area	26,100 km ²
Total Utsira formation Thickness	50–300 m
Layer#9 area	1600 m × 4900 m
Layer#9 thickness	3.5–26.3 m
Shale permeability	W–E: 0.001 mDarcy, N–S: 0.001 mDarcy, Vertical: 0.0001 mDarcy
Mudstone permeability	W–E: 2 Darcy, N–S: 10 Darcy, Vertical: 200 mDarcy
Utsira porosity (shale/mudstone)	35.7%
Residual CO ₂ saturation	0.02
Residual brine saturation	0.11
Relative permeability type	Corey/van Genuchten–Muller
Capillary pressure	None
Porewater salinity	3.3%
North–South geological slope	8.2 m/km, 5.8 m/km
CO ₂ feeder location	Main feeder: W–E: 516 m, N–S: 1210 m, bottom mudstone Secondary feeder: W–E: 925 m, N–S: 2250 m, bottom mudstone

In order to examine the plume evolution within the topmost layer more closely, a 3D model of Utsira Layer #9 is created with detailed topography. It should be noted that only Layer #9, not the entire depth, is modeled because of the following considerations. To ensure the accurate capture of topographic effect on plume shaping, computational domain with considerable fine mesh resolution has to be modeled based on geological survey data. The computational effort and thus the feasibility of highly detailed model of the entire Utsira formation is very intensive and time consuming. Secondly, CO₂ has to breakthrough several layers of relatively low permeability shale prior to reaching the topmost layer. While it is difficult to quantify the breakthrough of gaseous CO₂, the quantification of CO₂ feeding into the topmost layer (Layer #9) is rather reliable. Therefore, a model of only the topmost layer (Layer #9) could provide an ideal platform to investigate the effect of various parameters such as topography on the shaping of CO₂ plume, as well as it could be used for optimization purpose to achieve high efficiency sequestration while maintaining an affordable computational effort and cost.

A reservoir model with dimension of 1600 m × 4900 m with varying thickness is constructed. It covers the portion of Utsira formation where the plume, shown in Fig. 11, resides. As mentioned earlier, the topography of this portion of Utsira formation is accurately modeled based on seismic geological survey data provided by Zhu and Lu of the University of Indiana with 50 m × 50 m mesh resolution (Zhu and Lu, 2012). Because only Layer #9 is modeled, the thickness of the computational domain varies from 3.5 to 26.3 m with an average thickness of 11.3 m. However to accurately capture the accumulation and upward and lateral movement of CO₂, 37 layers are used along the thickness. The topmost layer and the bottom two layers are designated to represent the low permeability shale, while the 34 layers in the middle are assigned the properties of mudstone. In the 3D Layer #9 model, permeability anisotropy is considered with west-east permeability of 2 Darcy, north-south permeability of 10 Darcy, and vertical permeability of 200 mDarcy. 3D overview of the Layer #9 model is shown in Fig. 11.

Table 2 summarizes the hydrogeological properties of the Layer #9 model.

It should be noted that in the 3D Layer #9 model, the source of CO₂ is identified as “feeder” but not “injector” to emphasize that CO₂ is supplied from the lower aquifer through leakage pathways rather than by direct injection. Since the actual CO₂ injector is located at about 200 m under Layer #9, information of injection rate recorded at the injector is not applicable for the CO₂ feeders in Layer #9 model. To determine the CO₂ feeding rate to Layer #9, seismic surveys of CO₂ distribution are used to obtain its volume under in situ conditions, and then converted to mass flow rate. Information of CO₂ accumulative mass provided by Zhu and Lu is summarized in Table 3 (Zhu and Lu, 2012).

Table 3 Accumulative CO₂ mass in Layer #9, 1999–2008

Year	Accumulative mass (kg)	Yearly feeding mass (kg)	Feeding rate (kg/s)
1999	0.00	0.00	0.00
2000	1.82×10^7	1.82×10^7	0.577
2001	5.52×10^7	3.70×10^7	1.17
2002	9.49×10^7	3.97×10^7	1.26
2003	1.45×10^8	5.01×10^7	1.59
2004	2.13×10^8	6.80×10^7	2.16
2005	3.07×10^8	9.40×10^7	2.98
2006	4.34×10^8	1.27×10^8	4.03
2007	6.03×10^8	1.69×10^8	5.36
2008	8.20×10^8	2.17×10^8	6.88

Note: Zhu, C., Lu, P., 2012. Indiana University (Private communication).

**Fig. 12** Simulated CO₂ migration in Layer 9 of Utsira formation, 2000–2008.

Table 3 gives the CO₂ accumulation in Layer #9 from 1999 to 2008. It can be seen that CO₂ feeding rate to Layer #9 keeps on increasing for the recorded nine years. Recalling the analysis of secondary sealing effect given for the previous cases, it is the pressure gradient between the gaseous CO₂ phase pressure at lower aquifer and the capillary pressure of the overlying shale layer that determines the breakthrough of CO₂ and its flow rate. When breakthrough first occurs, the pressure gradient just breaks the equilibrium state, resulting in relatively low breakthrough mass flux to Layer #9. However, as more CO₂ accumulates, the pressure gradient gradually increases and leads to increasing breakthrough mass flux as depicted in **Table 3**. A nine-year average feeding rate of about 2.89 kg/s can be obtained from **Table 3**. Both the nine-year average value and the values in **Table 3** have been considered in the simulations.

The significant north-trending plume finger is rather perplexing for regular pressure-gradient driven Darcy flow. Analysis suggests three possible explanations to the cause of prominent north-trending CO₂ fingering along the ridge: (1) significantly higher permeability applied to the ridge, (2) existence of north-south geological slope which enhances the buoyancy-driven migration along the ridge, and (3) existence of a secondary (or even multiple) CO₂ pathways under the ridge. The hypothesis of significantly higher permeability at the ridge can be easily ruled out since no such evidence is obtained from the geological survey. It is still under debate whether geological slope should be considered when analyzing the CO₂ migration in Utsira formation. Chadwick and Noy's work has suggested two possible values of geological slope based on the seismic images of the cross-section of the Utsira formation, which are 8.2 m/km and 5.8 m/km (Chadwick and Noy, 2010).

The simulation time is set at nine years, which corresponds to the injection period of 1999–2008. CO₂ plume migration at the topmost layer is examined for each year. Considering all the uncertainties mentioned above, a total of nine simulations are performed until a good history-matching is obtained, as shown in **Fig. 12**.

As can be seen by history matching, the 3D detailed Utsira Layer #9 model has generated satisfactory simulation results. In summary, five major conclusions can be made as follows. First, the simulations show that the permeability anisotropy should be accurately modeled. Vertical-to-horizontal anisotropy close to 10:1 is needed to accurately capture the upward migration of CO₂. Horizontal anisotropy of 2:10 is needed to capture the northern spill of CO₂ into the north-trending ridge. Secondly, a secondary feeder is likely to exist directly under the north-trending ridge to generate sufficient plume migration along the ridge. It suggests multiple pathways for CO₂ breakthrough from the lower aquifer structure. Thirdly, the fact that injection gas being CO₂–methane mixture is very important in modeling since the presence of 2% methane enhances the buoyancy. Fourthly, it is critical that time-

dependent feeding of CO₂ is modeled. This is consistent with the behavior of CO₂ path flow breaking the capillary pressure barrier, as noted before for the secondary-sealing effect in case of Mt. Simon formation. And finally, simulation results suggest strong mobility of gaseous CO₂ under the caprock (shale) without major leakage, implying that the caprock serves quite well as the non-permeable CO₂ barrier while exerting little resistance for the lateral flow of CO₂ underneath.

The simulation studies of the two actual large scale identified deep saline aquifers provide important insights and best practices for obtaining accurate simulations of GCS using TOUGH2.

Conclusion

In this chapter, first the multi-phase fluid mechanics and other mechanisms relevant to geological sequestration of CO₂ are discussed including the processes and features of GCS that become important at various spatial and temporal scales. Then rest of the chapter is devoted to the modeling and simulation of saline aquifer geological carbon sequestration (SAGCS) for two large scale industrial projects, namely the Mt. Simon in Illinois and Sleipner/Utsira in Norway. The numerical simulations are based on the DOE simulator TOUGH2. The simulations show that they can provide satisfactory information about the plume migration in the formations over large spatial and time scales and therefore can be used to assess the viability of large GCS projects a priori before actual deployment. As to the recommendations for the future work in GCS, the real-life SAGCS projects such as the ADM Mt. Simon project, Sleipner project and others should be continually studied over the years as more detailed field data becomes available. In addition, optimization studies for large scale SAGCS projects should be performed for greater storage efficiency and reduced plume migration.

Acknowledgements

The author is grateful to his former graduate student Dr. Zheming Zhang who performed many of the numerical simulations reported in this paper.

Introduction

Composite materials are defined as the combination of two or more different materials to produce unique and superior materials. But now a day's composites are described as reinforced plastics. Composites are the most widely used materials due to their special characters like adaptability to different situation while combine to other materials to serve various purpose and exhibit desirable properties. There are so many composites like metal matrix composites, nano composites, fiber reinforced composites and hybrid composites commonly used in various industries. Composite materials can provide unique advantages in comparison with materials like metals, wood. The primary driver and advantage in the adoption of composites is the lightweight properties. In transportation, these light weight composites can save more fuel and improve acceleration. In sporting equipment, these materials allow for longer drives in golf, faster swings in tennis, and straighter shots in archery. In production of wind energy, if the blade weight is less, more power the turbine can produce. Besides these composites acquires more beneficial properties like: Non-corrosive, Non-conductive, Flexible, will not dent, Low maintenance, Long life, Design flexibility. Based on structures there are three main classifications of composites we have:

- (1) Particle-reinforced (large-particle and dispersion-strengthened) – These are composed of particle of one or more material is dispersed in a matrix of another material to make it strong and stable.
- (2) Fiber-reinforced (continuous (aligned) and short fibers (aligned or random) – In this case long fiber of one material is incorporated in the matrix of other material like polymer, which turns out to be extremely strong.
- (3) Structural (laminates and sandwich panels) – While there are layers of two or more different material are bonded together by sandwiching two layers of strong materials.

The most common type matrix is like polymer matrix, metal matrix and ceramic matrix composites, as are natural composites such as wood. There are so many research work has done for the production of suitable composite materials, but they are all hazardous and emitting materials, harmful for environment. Hence ecological concerns have resulted in renewed interest in natural materials and recyclability and environmental safety are becoming increasingly important issue in the case of composite production. Now our attention is focused on sustainable manufacturing of composites which may be green composites and are environment friendly.

Manufacturing is a word derived from middle French in Medieval Latin Manufactura (Manu + Factura) which means made by hand. From the very early stage ancient humans are applying different manufacturing techniques and developed gradually. But the first signs of modernization in manufacturing method were seen in the mid of sixteenth to seventeenth century. Manufacturing is a series of processes which includes selection of raw materials, production or fabrication of objects, building or constructing, assembling the parts, inspection or examination and finally dispatching, [Fig. 1](#).

Modernization is going at faster rates so as to meet the needs of human beings the Industrial sectors of many of the countries are following modern manufacturing techniques. Along with the modernization and development of techniques, human being should see that new or existing method is not harming the natural resources and is not disturbing the balance of the ecosystem. Since the natural resources are not in adequate amount, their utilization should be optimized for future generations. The use of natural sources and hence energy by the human resource is increased exponentially [Fig. 2](#).

There are so many conventional manufacturing process are there like casting, moulding, forming, machining, joining, additive manufacturing, rapid manufacturing etc. During these different modern methods of manufacturing of composites, the waste disposed are very harmful and has an enormous detrimental effect on the environment. For manufacturing of composite materials, workers have to handle very harmful heavy metals like lead, zinc, cadmium and also hazardous air pollutants including carbon materials, gaseous pollutant, benzene is released from cupola furnace, very harmful to health. For cutting purpose, fluids used such as water based – emulsions (soluble oil), chemical solutions (or synthetic fluids), mineral oils – fatty oils, composed oils, extreme pressure oils (EP). These metal working fluids can be used once and thus after the work they are thrown into water bodies, land causing hazardous pollution. Hence there should be continuous examination of pollutant levels at each and every stage of manufacturing. Now a days in any developing country a common word is being echoed in every industrial sector i.e., "Green Technology". Due to different types of production techniques there have been many greenhouse gases released into the atmosphere since 100 years. This is the main cause of the phenomena 'global warming'. And now for our sustainability, it's the time to save our planet from the effect of these harmful gases. Hence many sustainable techniques and environment-friendly operations have been standardized in every industry. Again a huge amount of energy is consumed during conventional manufacturing methods. In order to reduce that usage, industries are adopting green technologies. Green technologies are based on four R factor,

Fig. 1 Sequence of manufacturing.

Fig. 2 Comparison between energy consumption and availability of resources.

Refuse, Reduce, Reuse and Recycle which can optimize resource consumption, reduce wastage, adopt recycling and reuse techniques, so that the cost of production can also be optimized.

There are so many different ways can be adopted for green manufacturing technologies.

Operation of Energy Audits-The important step for green sustainable manufacturing is conducting the energy audit on day to day basis for checking where energy is consumed in higher amount. After that it will be replaced with green technical equipment. As there is limited availability of fossil fuels and the global ecological balance is also being disturbed, hence the only survival strategy is to minimize the energy consumption. Hence use of green products in manufacturing, contributes towards use of less energy and production would enhance the reduction in carbon emissions.

Use of Renewable and alternative energy – Instead of using conventional power, produced by fossil fuels, the need of hour is to use renewable energy resources like solar, wind, tides, biomass etc. Many governments provide incentives and tax free production for production of power from green technologies.

Application of 3 R's (Reduce, Reuse and Recycle) –The production cost can also be reduced by recycling the waste left after manufacturing of materials.

Minimize the usage of water – There are so many industries like textile, leather and construction discharge their waste directly to the water bodies which again polluting the water and also harmful for us.

The real meaning of green technology is not only regulate the pollution or recycling process but also reduces the energy consumption and emission of harmful materials in each and every stage of manufacturing. Green Manufacturing focuses on primary goals such as minimization of emissions, effluents, accidents, use of virgin and non -renewable, energy resources, life cycle cost, product and services. The following diagram, **Fig. 3**, represents the development of an industry and hence A country or a industry said to be developed only that time when it will adopt modern green technology with highest production rates. Its development is achieved step wise.

Green Manufacture of Metal Composites

Metal matrix composites are not used widely as polymer composites but at present it generates an wide interest due to its high strength, fracture toughness and stiffness. They can withstand elevated temperature than polymer composites. While most of the metals are used as matrix for the composite, a reinforcement material should use to stabilize the composite over a range of

Fig. 3 Result of green manufacture.

Fig. 4 Characterization of Nano composites based on application.

temperature and non-reactive also. Generally light metals are responsive for low temperature applications. For aircraft applications titanium, aluminum and magnesium are the popular matrix. High modulus reinforcements are used for the metal matrix where it has to offer high strength. The strength-to-weight ratios of resulting composites can be higher than most alloys.

The purpose of using reinforcing constituent in composites is to serve as heat resistance or conduction, corrosion resistance and also provide rigidity. A reinforcement that embellishes the matrix strength must be stronger and stiffer than the matrix and capable of changing failure mechanism to the advantage of the composite. This means that the ductility should be minimal or even nil the composite must behave as brittle as possible. As reinforcing agents fibers, fabrics particles or whiskers can be used for the metal composites. Fibers are essentially characterized by one very long axis with other two axes either often circular or near circular.

Metal Nano- Composites

Nano-composites are a new generation of improved materials, can be formed by mixing one or more different materials at the nano scale in order to control and develop new and improved structures as well as properties (Fig. 4). The term nano-composite includes a wide range of materials from three-dimensional metal matrix composites, two-dimensional lamellar composites, and nanowires of single dimension to zero-dimensional core shells.

The properties of nano-composites depend not only upon the individual components used, but also upon the morphology and the interface characteristics. As compared to individual materials, nano-composites can enrich the properties such as improved friction and abrasion resistance, fouling resistance, super hydrophobicity, super hydrophilicity, thermal energy transport, electronic and ionic transport, and liquid transport displayed for a wide range of engineering applications. As per (Freedonia, 2008), the demand for nano-composites in 2011 reached 150,000 TPA in USA. The use of nano composites will be huge by reducing the price of nano materials and increase in production. It is expected that nano-composites by 2025 will be the US \$9 billion market, with volumes nearing 5 million tons.

Multifunctional nano-composites are of great interest due to their synergy and developed properties compared to their base counterparts (Akbulut *et al.*, 2009; Gobin *et al.*, 2004; Yang and Ko, 2008). Noble metal-based systems are incorporating frequently to obtain the desired functional nano-materials. Research has been made in incorporating noble metals on semiconductor metal oxides such as TiO₂ and highly conductive nanomaterial such as CNTs using any surfactant or linkers (Jose *et al.*, 2009; Peining *et al.*, 2011). It is proved that at nano scale a vast changes of physical, chemical and biological properties of any materials occurred from their bulk counterpart because of the quantum confinement. For instance, gold and silver nanoparticles have the ability to absorb visible light at certain wavelengths, which depend on the size and shape of the nano – materials.

There are so many different methods are invented for the synthesis of nano materials like chemical, physical, and biological methods. But some these chemical or physical methods have resulted environment contamination by producing a large amount of hazardous byproducts and gases (Amato *et al.*, 2011).

Hence most of the research works are focused on Green Technology, including a clean, safe, nontoxic and eco-friendly synthesis methods, without the use of high pressure, energy, temperature, and toxic chemicals (Pallavicini *et al.*, 2010). Through the biological methods nano-materials can be synthesized from the extracts of plant, bacterial, fungal species, and so forth (Dallas *et al.*, 2011).

Nanoparticles of silver have been found to exhibit interesting antibacterial activity (Deshmukh and Composto, 2006). Recently, materials have been developed (mainly textiles) incorporating silver nanoparticles, which possess very interesting antimicrobial activity. For this unique property of Ag, the plastic containing silver can be used in medicines to reduce infections and also preventing bacteria colonization on plastic devices such as prostheses, catheters, vascular grafts, and dental materials (Damm and Munstedt, 2008). The generation and propagation of micro-organisms on plastic medium can occur under ideal temperature and humidity conditions causing irritation and infection. Hence the materials made of polymers can protect against micro-organisms in order to suppress their growth and dissemination. There are so many research work has reported the use of silver nanoparticles (AgNPs) to form composites with polymers such as polyvinyl alcohol, polypyrrole, poly-vinylidene fluoride, chitosan, and cellulose. But for the formation of polymer-silver nano-composites, it is required to control the size of the nano particles and the distribution of nano particles should be uniform (Mohan *et al.*, 2006).

Ag – Polystyrene nano composite

Green synthesis of Ag nano particles was done by using orange peel as reducing agent and then these nano particles were incorporated in polystyrene matrix forming Ag- polystyrene nano composite film.

Experimental

Green Synthesis of Silver Nanoparticles: 200mg of orange peel was taken to crush and 20 ml of toluene was added to it with continuous vigorous stirring at 600C to prepare the orange peel extract. After this the extract was centrifuged at room temperature for 5 min at 7000 rpm. In another flask 1 mmol/ml silver nitrate was dissolved in 20 ml of toluene with again vigorous stirring at the temperature of 700C for 5 min. Then 5 ml of orange peel extract was added to silver nitrate solution which changes to brown colour indicating reduction of silver ion.

Synthesis of Green AgNPs/PS Nano-composite Film: Various methods are employed to prepare antimicrobial AgNPs/PS nano-composite (Tripathi *et al.*, 2011). Here solution method is used to synthesize antimicrobial AgNPs/PS films. 2 gm of polystyrene was mixed with silver nano particles, dispersed in toluene. During the addition of polystyrene the solution was stirred vigorously and continuously at 600C. Finally the solution was cast in a glass plate and keep it at room temperature for 24 h. to evaporate the toluene. Thus nano composite film was prepared.

Characterization

Nano-composite film was characterized spectro-photometrically using X-ray diffraction, Bruker D8 Discover, the size of green synthesized AgNPs was analyzed through Zetasizer, Nano series, HT Laser, ZEN3600 (Molven Instrument, UK).

Transmission Electron Microscopy (JEM-1011, JEOL, Japan) was employed to characterize the size, shape, and morphologies of formed nano-composite at voltage of 80–100 KV, while Thermo Scientific, Nicolet 6700, FT-IR spectrophotometer was used for recording the infrared (IR) spectrum.

With the help of Energy Dispersive Spectroscopy (EDS) analysis the formation of elemental silver was confirmed. Elemental analysis on single particles was carried out by Oxford Instrument, Incax-act, equipped with Scanning Electron Microscopy using (JEOL-FE SEM, Japan).

Ag- Chitogannano – Composite

Ag nano particles are becoming significant and important to all scientist as it attributes towards biological activities such as antitumor activity, antimicrobial activity and enhance the immunity system (Gu *et al.*, 2003; Dutta *et al.*, 2011). There are so many methods are applied for producing silver nanoparticles (Ag NPs) like both physical and chemical approaches such as sono-chemical and electro-chemical methods, thermal decomposition, laser ablation, microwave irradiation, etc. (Kim *et al.*, 2005; Bae *et al.*, 2002; Zhang *et al.*, 2004). But these methods have some limitations as using toxic and hazardous chemicals, consuming high energy. So interests are grown to synthesis of Ag- nano composites by green technologies (Panigrahi *et al.*, 2005; Qian and Yang, 2005; Huang *et al.*, 2006; Pal *et al.*, 2008, 2007). Therefore, green synthesis is eco-friendly processes in chemistry, in chemical technology and engineering. These processes are becoming more popular and essential to reduce the environment pollution (Thuesombat *et al.*, 2014). In green synthesis

of these nano composites, mainly natural polymers (chitosan, etc), sugars, enzymes, microorganisms, plant extracts as reductants (e.g., lemon aqueous extract, Azadirachita indica aqueous leaf extract, kumquat aqueous extract, and capping agents are used (Mittal *et al.*, 2013; Prabhu and Poulouse, 2012; Gopinath *et al.*, 2013; Bar *et al.*, 2009; Rafique *et al.*, 2016). These natural sources are abandoned and reactions are also simple, one step, cost-effective, energy efficient, forming more stable and environment friendly composite materials (Kharissova *et al.*, 2013; Badawy and Rabea, 2011; Kong *et al.*, 2010; Ahmed and Saiqa, 2015; Benelli, 2016; Ahmed *et al.*, 2016).

Experimental

River leaf creeper extract was used for green synthesis of Chitosan- Ag nano particles with the help of microwave without using any hazardous chemicals. At low concentration of River leaf creeper extract, nano composites are produced. Moreover, the synthesized chitosan/Ag nano-composites also showed their anti-bacterial activity on E. Coli bacteria.

Fresh River leaf creeper first boiled with de-ionised water at 100°C for 10 min and filtered to obtain a juice extract from river leaf. This extract is used as reducing agent. 0.01 M 1 ml AgNO₃ solution was mixed with chitosan solution, 1.5 mg/ml of which is in 2% acetic acid solution. Then in this solution river leaf creeper extract was added for reduction of Ag metals at 70°C with constant stirring for 90 min. During the reaction the colour of the solution changes time by time. Finally the solution was centrifuged at 10,000 rpm for 15 min and washed with DI water to remove undesired products. The average particle size of the as-prepared chitosan/Ag nano-composite is ~15–41 nm.

Characterization

The absorbance spectra of particle solutions were analyzed by UV–vis spectrophotometry (UV-675; Shimadzu). Fourier transform infrared spectroscopy (FTIR) of chitosan/Ag nano-composites were done by using a Renishaw 2000 confocal Raman microscope system. The phase structure of chitosan/Ag nano-composite was obtained, using X-ray diffractometer (Rigaku Dmax-B, Japan) with Cu K α source operated at 40 kV and 100 mA. A scan rate of 0.05°–1° was used for 2 θ between 10° and 80°. The particle size and surface morphology of chitosan/Ag nano-composites were analyzed by transmission electron microscope (TEM) with a Philips Tecnai F20 G2 FEI-TEM microscope (accelerating voltage 200 kV).

Graphene based Ag nano composites

The main constituent of graphene is carbon atom and they are bonded with each other in a repeating pattern of hexagon (Grigorenko *et al.*, 2012). For this reason graphene has a wide range of application in the field of electronic, energy storage and super capacitor, batteries (fuel cells, solar cells), and bioscience/biotechnologies. Graphene-based nano-composites again shows unique properties, which are useful for various biomedical applications including drug/gene delivery, imaging, antibacterial and anti-cancer activities (Khan *et al.*, 2015a,b). The important role of graphene in the composites is acting either as a functional element or a substrate for immobilizing the other constituents such as metal likes silver, gold, zinc oxide, copper etc (Xu *et al.*, 2008). In recent years, it was investigated that (GO) based Ag nano-composites are also very useful for many applications and several methods like chemical. (Nossol *et al.*, 2014), thermal (Chen *et al.*, 2011), microwave (Hassan *et al.*, 2009), and green methods have been reported for the synthesis of GO- Ag nano composites. While GO-Ag nano composites are synthesized through chemicals reduction method, some of the chemicals such as Hydrazine (N₂H₄), Sodium borohydride (NaBH₄), Dimethyl hydrazine (C₂H₈N₂), Hydroquinone (C₆H₆O₂), Sulphuric acid (H₂SO₄), and Aluminum powder (Al), involved in the reduction and functionalization of graphene oxide, have highest number of toxicity. Hence here also Green technologies are adopted for reduction of graphene oxide. Natural reducing agents like plant extracts have been considerably exploited due to their low cost, bulk availability and biocompatibility for these metal nano-composite (Khan *et al.*, 2015a,b).

Experimental

Silver nano materials have excellent anti-microbial activity. Hence these nano materials incorporated in graphene network for packaging and bio-medical applications (Sahu *et al.*, 2015).

GO was prepared by the oxidation of natural graphite powder according to modified Hummers method (Chen *et al.*, 2013).

Sapodilla fruit was washed with first distilled water and peeled off manually. Then the peels were cut into very small pieces. About 10 gm of this sapodilla peels were dipped into distilled water around 1h. Thus the extract obtained, filtered for further experiment.

Another flask contained 100 ml 0.1 M solution of AgNO₃ mixed with 200 ml of 0.1 M aqueous ammonia solution to prepare 0.1 M of silver Ammonia solution. Then 1 ml of GO (0.1 mg/ml) and 20 ml of this silver ammonia solution are mixed properly with constant stirring. Next 2 ml of sapodilla peel extract was added to the mixture with stirring and treated with sunlight. Within a few seconds, the brown coloured solution changed to dark yellowish brown solution indicating the formation of the composite materials. Finally the solution was covered with aluminum foil and kept it into dark place for complete and uniform deposition of Ag nano particles on GO sheet. After that the solution was centrifuged for 10 min at 4000 rpm and the final compound was washed with distilled water again and again.

Characterization

The absorbance spectra of the prepared sample was analyzed by UV–vis spectrophotometry (UV-675; Shimadzu). Fourier transform infrared spectroscopy (FTIR) of GO/Ag nano-composites were done by using a Renishaw 2000 confocal Raman microscope

Scheme 1 Reaction mechanism for synthesis of Ag- Chitosan- polyethylene glycol nano Composites.

system characterized by UV, FT- IR, SEM and TEM spectra. The surface morphology of composite materials can observed through TEM spectra.

Ag- Chitosan- polyethylene glycol nano composites

The green synthesis method can be used to synthesize Ag- Chitosan- polyethylene glycol also. The concept of green synthesis was adopted to reduce the pollution of environment as in conventional method so many toxic reagents were used. Besides, it also utilizes a non-toxic stabilizer in forming Ag NPs (Raveendran *et al.*, 2003; Shameli *et al.*, 2010). It is reported that the exclusion of NaBH₄ in the synthesis made it “greener” as compared to the method reported by Huang *et al.* (2004).

After formation of nano particles, a stabilizer should use to control the formation and dispersion of metal nanoparticles. Many research work established that polymer can be used as stabilizer to control the particle growth, stabilize the metal dispersions and limit the oxidation of the particle (Sun *et al.*, 2001; Pimpang *et al.*, 2008). Chitosan(Cts) is excellent biocompatible, biodegradable, non-toxic and bioactive material. Polyethylene Glycol (PEG) is a water-soluble polymer with a general formula H(OCH₂CH₂)_nOH. This polymer is widely used in the mechanical as well as pharmaceutical and cosmetic industries. This is also a good stabilizer for the nano composites where Ag nano particles are used.

Experimental

In this green synthesis AgNO₃ solution was stirred with different times at moderate temperature, reducing the Ag metal to Ag⁺ ions. Chitosan solution was mixed to PEG solution to produce Cts/PEG solution. Next, to this solution Ag⁺ ion containing solution was added which reacted with the Cts/PEG to form metallo-polymer [Ag/Cts/PEG]⁺ (Equation 1). This metallo polymer was stirred at a moderate temperature of 60°C according to varying stirring times to form Ag/Cts/PEG nano-composites (Equation 2). In this process, Ag⁺ was successfully reduced to Ag⁰ to form Ag NPs **Scheme 1**.

Characterization

The influence of the stirring times on the optical properties, structures and morphologies of silver nanoparticles was characterized by the ultraviolet-visible (UV-vis) spectroscopy, X-ray diffraction (XRD), transmission electron microscopy (TEM), scanning electron microscopy (SEM) and Fourier transform infrared spectroscopy (FTIR).

Cu- magnesium oxide nano composite

The MNPs are more active than their particulate metal counterparts due to their properties, small sizes and large surface areas. Among MNPs, copper nanoparticles (Cu NPs) have attained a particular attention due to cheapness and availability compared to other metal nanoparticles (Pourtehdal *et al.*, 2009; Karunakaran *et al.*, 2010; Ghosh *et al.*, 2015). Despite the advantages of Cu NPs, the stability of nano particles were inevitable. The synthesis of these nano particles through heterogeneous catalysts is one of the best ways to overcome the agglomeration of MNPs (Panin *et al.*, 2004; Panin *et al.*, 2005; Jung *et al.*, 2005; Takada *et al.*, 2008; Dhineshbabu *et al.*, 2014). Recently, various research groups reported the green synthesis of MNPs such as TiO₂ (Khade *et al.*, 2015) graphene oxide (Choi *et al.*, 2015), Fe₃O₄ (Fekri *et al.*, 2015), bentonite (Issaabadi *et al.*, 2017), perlite (Vartooni *et al.*, 2016) and etc. In this regard, MgO has been used widely as an efficient heterogeneous catalyst in organic reactions due to its good chemical and thermal stability, low cost, high surface area, ease of handling and high catalytic activity reusability (Julkapli and Bagheri, 2016). Plants extract mediated synthesis of NPs can be beneficial for preparing nano-metals to control the size, shape and distribution size. The green approach for the synthesis of Cu nano particles by using plants extract were eco-friendly, compared to other physical and chemical methods. This green methods included the use of nontoxic solvents, simple work-up procedure, very mild reaction conditions, cleaner reaction profiles. These reactions involved limited emission of toxic and dangerous materials, without using of surfactant, capping agent and or template, elimination of high pressure, energy, temperature and very cost effective (Sathishkumar *et al.*, 2009; Bordbar *et al.*, 2017; Bordbar, 2017).

Cassythafliformis L. from the Cassythaceae family was a medicinal plant of tropical region of Asia and America which mainly well known for the treatment of cancer. In modern medical research, C. filiformis has been reported to constitute so many number of different biologically active chemical compounds can be used for human health applications. The aqueous extract of Cassythafliformis L was used for reduction of metal particles into stable nanoparticles without application of poisonous chemicals and harsh reaction conditions.

Scheme 2 Reaction mechanism for synthesis of Cu- Magnesium Oxide Nano Composite.

Experimental

Cu/MgO nano-composite via a new, fast, simple, green, cost effective and ecofriendly process by using *Cassipoupa grandiflora* L. extract as stabilizing and reducing agent for the reduction of Cu^{2+} ion to Cu^0 .

50 gm of dried powder of *Cassipoupa grandiflora* L fruit was added to 250 ml of double distilled water with constant stirring at 70°C for 30 min in magnetic heating stirrer. Then the extract was centrifuged at 7000 rpm and filtered.

To 10 ml of 5 mM $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$, 100 ml of freshly prepared plant extract was added with vigorous shaking until the colour of the solution was changed to yellow to dark. After that the solution was centrifuged for 30 min at 7000 rpm and filtered. The filtrate then washed thoroughly with n-hexane and ethanol to remove impurities, **Scheme 2**.

Next 25 ml of 5 mM $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ was added drop wise to the plant extract and also 1 gm of MgO was added to the mixture with constant stirring at 80°C for 4 h. Then the solution was centrifuged to separate Cu-MgO nano composite and washed with distilled water and then dried at 90°C for 2 h.

Characterization

FT-IR spectra were recorded on a Nicolet 370 FT/IR spectrometer (Thermo Nicolet, USA) using pressed KBr pellets. The formation and the size of nanoparticles was analyzed by UV-Visible spectral analysis on a double-beam spectrophotometer (Hitachi, U-2900). The morphology of the Cu/MgO nano-composite were identified by transmission electron microscope (TEM) using a Philips EM208 microscope operating at an accelerating voltage of 90 kV. Field emission scanning electron microscopy (FE-SEM) was performed on a cam scan MV2300. The Chemical analysis of prepared nanostructures was analyzed with EDS (energy dispersive X-ray spectroscopy). X-ray diffraction (XRD) mensuration were done by using a Philips powder diffractometer type PW 1373 goniometer ($\text{Cu K}\alpha = 1.5406 \text{ \AA}$). The scanning rate was 2° min^{-1} in the 2θ range from 10 to 90° .

Metal Oxide nano composites from solid waste

Recently there are so many research work has been reported on synthesizing nano sized metal oxide based catalysts prepared by very simple, versatile and ecofriendly methods to get the suitable texture and chemical composition of catalysts. In this purpose solid waste can be used for green synthesis of nano composites (Fan *et al.*, 2008; Kargbo, 2010; Matos *et al.*, 2011; Esparza *et al.*, 2011; Zhuo *et al.*, 2012). Some of the composites produced from sewage sludge based can be used as an adsorbent for adsorbing NO_2 (Pietrzak and Bandosz, 2008).

Iron oxide nano composites, having variable surface area and different size of porous sites, facilitate the adsorption and transport of various species in the reacting system. They also contain a large number of active sites which can provide superior adaptability and sustainability for various applications in the field of energy and environment, semiconductors, medicinal use. They are also useful for inorganic and organic contaminant degradation (Cao *et al.*, 2007; Oha and Park, 2011; Xu and Wang, 2011). There are so many work has been done to produce iron oxide nano composites. But mostly they used hazardous chemicals and sophisticated instruments. The treatment of solid industrial waste to synthesis of nano composites by Electro chemical method is one of the economic, simple and short treatment. Theory of EC methodology is described in the supporting information (SI).

Experimental

Iron oxide nano composites were prepared from solid waste, calcined at different temperatures. The composites were then characterized by using different methods to evaluate their structures and morphology.

At first the solid waste was spread over a glass plate to dry for 2–3 days, until the mass became constant. Then 5 gm of this waste was taken into a silica crucible for calcination at different temperatures for 3h in muffle furnace, **Scheme 3**, shows the graphical representation of the preparation of iron oxide NCMs from EC solid waste. Experimental procedure for EC treatment and generation of sludge is given in supporting information (SI). The solid waste heated to 100°C and then the temperature was gradually increases from 100°C to 300°C , up to 1000°C . After that the calcined waste was furnace cooled.

Scheme 3 Synthesis of metal oxide nano composite from solid waste.

Characterization

Thermo-gravimetric and differential thermal analysis (TGA and DTA) were carried out using Perkin ElemerPyris Diamond thermo-gravimetric (TG) analyzer in air atmosphere at the heating rate of $10^{\circ}\text{C}/\text{min}$ with air flow rate of 20 ml min^{-1} in the temperature range $20\text{--}1000^{\circ}\text{C}$. Powder X-ray diffraction (PXD) patterns were recorded on a Bruker AXES D8 advance powder X-ray diffractometer operating at 40 kV and 30 mA using Cu K α radiation ($\lambda = 1.5418\text{ \AA}$) in the angular range $10^{\circ}\text{--}90^{\circ}$. The experiment was done at a scan rate of $0.02^{\circ}/\text{step}$ and 0.5 s per step. The observed PXD patterns were analyzed by comparing with the powder diffraction files available in the joint committee on powder diffraction standards (JCPDS) database. Field emission scanning electron microscope (FE-SEM: QUANTA 200-FEG) was used to analyze the surface topography. The elemental analysis of the prepared iron oxide NCMs was performed using energy dispersive X-ray analysis (EDX) accessory by 5%–10% error of element contents.

Au- Iron oxide nano composite

In many cases super magnetic iron oxide nano particles were often coated with Ag or Au metal, supporting a localized plasmon resonance and also protects the magnetic core from many chemicals. These metallic core played an important role in surface chemistry or enhancing the dispersion and compatibility in biological media (Yu *et al.*, 2005; Wei *et al.*, 2008; Levin *et al.*, 2009; Wei *et al.*, 2009; Song *et al.*, 2010; Kim *et al.*, 2011; Miao *et al.*, 2011; Bhana *et al.*, 2012). Hence Au- Fe_xO_y nano particles can be used as multimodal contrast agents for isolating and purifying the protein molecules like DNA in biomedical imaging. These nano particles also played important role as photothermal agents for hyperthermia-mediated cancer therapies (Mandal *et al.*, 2005; Smolensky *et al.*, 2011; Meledandri *et al.*, 2011; Jin *et al.*, 2010; Aaron *et al.*, 2006; Park *et al.*, 2007; Ma *et al.*, 2009; Mohammad *et al.*, 2010; Xie *et al.*, 2010; Wang *et al.*, 2009; Huang *et al.*, 2009). Despite their strong technological potential, in most of the studies, organic non-polar solvents, high temperatures or high concentration of non-bio-degradable surfactants were used for the production of Au- Fe_xO_y nano composites. All of these are negative factors from the perspective of sustainable manufacturing and lifecycle assessment, causing significant pollution of the environment, consumption of energy and increasing production costs (Kralisch *et al.*, 2015). Hence we must seek an alternative, greener methods for synthesizing Au- Fe_xO_y NPs, with minimum concerns for environmental impact upon scaled production.

Experimental

This is an optimized and highly reproducible method for synthesizing MGNs in aqueous alcohol, based on systematic adjustments in reagent concentrations and reaction conditions.

648 mg of 4 mmol FeCl_3 and 398 mg of 2 mmol $\text{FeCl}_2 \cdot 2\text{H}_2\text{O}$ solutions were mixed in 5 ml de-aerated de-ionized water. To this solution 15 ml of 28% NH_4OH solution was added drop wise over a period of 10 min. and immersed the solution in ultrasonic bath. Immediately Fe_3O_4 was formed as suspension. While iron salts were added to the NH_4OH solution, the anaerobic condition must be maintained. The mixture was then removed from ultrasonic bath and agitated for 2 min by vortex mixing to generate a homogeneous dispersion. Colloidal Fe_3O_4 was precipitated keeping an external handheld magnet along the walls of the reaction tube, then re-dispersed in deionized water. This process was repeated again and again to remove weakly magnetized colloidal oxides. Finally the precipitation was separated and dried to take the weight.

20 mg of 5 kDa mPEG- NH_2 was dissolved in 1 ml of dry de-aerated methanol with stirring for 10 min. Then to this solution 4 μmol of CS2 (one equivalent, diluted with methanol) was added with stirring for 10 min. Then 4 μmol triethylamine was added to the mixture with continuous stirring for again 10 min, resulting in mPEG-dithiocarbamate (DTC). Absorption spectroscopy confirmed DTC formation by the appearance of a doublet at 255–295 nm (Zhu *et al.*, 2008). Then freshly prepared mPEG-DTC solution was mixed with 1 ml of colloidal Fe_3O_4 , dispersed in water (8 mg ml^{-1}) and incubated at room temperature for 1h. Aliquots were removed and air-dried for analytical characterization.

A 0.25-ml aliquot of freshly prepared dispersion of mPEG-DTC-treated colloidal Fe_3O_4 (1 mg) was taken and added to 4 ml of an aqueous solution of L-histidine (1 mg ml^{-1}). The pH of the solution was adjusted to 5–6 using 0.1 M HCl, then incubated at room temperature for 1 h. After that 0.6 ml of 1% w/v HAuCl_4 was diluted by 14.8 ml distilled water. The pH of this solution was

maintained at 9–10 by using 5 M NaOH. To the colloidal Fe_3O_4 – histidine solution, diluted HAuCl_4 solution was added with constant stirring for 20 min. Now the reaction mixture was treated with 20 mM N-methylhydroxylamine (NMH) for initiating the reduction. The NMH solution was added in 5 portion to the reaction mixture of 0.2 ml with constant stirring in each 5 min. During the reaction noticeable change in colour occurred. The magnetic nano composites were finally formed after 12 h at room temperature. The final range of pH would be 6–7. The produced MGNCs were separated by selective precipitation using a handheld NdFeB magnet producing linear field gradients of $1\text{--}3\text{ kG cm}^{-1}$. After 15–20 min magnetically unresponsive materials was removed by decantation. The residue was the again and again re-dispersed into water at twice the original volume with mild sonication, followed by magnetic precipitation, to yield MGNCs that were essentially devoid of non-magnetic gold NPs.

Finally 0.5 M solution of diethanol – DTC in methanol (DE-DTC; final concentration 2 mM) is used for removal of excess Fe_3O_4 from nano-composites. In a typical cleansing procedure, 20 μl of 0.5 M DE-DTC was added to 5 ml of final compound MGNCs (O.D. 0.4), followed by vortex mixing, keeping it in ultra sonicator for several seconds, incubation for 1h at room temperature, then two rounds of magnetic precipitation and re-dispersion in water.

Characterization

The prepared metal oxide nano composites was characterized by using transmission electron microscopy (TEM) using a Tecnai-T20 microscope (FEL, Hillsboro, OR, USA). TEM samples were prepared by floating carbon-coated grids on top of an aqueous NP dispersion for 30 min, followed by removal of the grid and drying in air for at least 60 min prior to analysis. Energy-dispersive X-ray (EDX) analysis by scanning transmission electron microscopy (STEM) was done by using a Tecnai G2 T20 microscope (FEL) equipped with a LaB6 filament and X-Max 80 silicon drift detector (Oxford, UK), with data collected by a high-angle annular dark field (HAADF) detector (Fischione, Export, PA, USA) and recorded by a $2\text{ k} \times 2\text{ k}$ CCD imaging camera (Gatan, Pleasanton, CA, USA) using Inca software (ETAS, Stuttgart, Germany). Atomic absorption spectroscopy (AAS) was performed with a Perkin-Elmer (Waltham, MA, USA) 3110 spectrometer, using materials dissolved in aqua regia.

Ceramic Composite

Now a days it has been reported that carbon fiber reinforced silicon carbide matrix composites were applicable in the field where high specific strength with suitable fracture toughness at elevated temperature were required like automotive breaks, high efficiency engine systems, chemical reactor and space vehicle (Rak, 2001; Naslain, 2005; Zhang *et al.*, 2008). But there were so many limitations for synthesizing these composites such as difficulties in reproducibility, use of expensive equipment and involvements of hazardous chemicals.

Several methods can be use to fabricate carbon- silicon carbide composite materials like carbon vapor infiltration, polymer impregnation and pyrolysis, liquid silicon infiltration, sol-gel method etc. But all these methods have merits and demerits. According to a research work this composites can synthesize by soft solution approach which is simple, rapid and eco-friendly process.

Carbon Fiber Reinforced SiC

Experimental

Water soluble colloidal 40% by wt silica, sucrose, boric acid and zirconiumoxychloride were taken as raw materials for the production of silica, carbon, boron oxide and zirconium di-oxide. In this soft solution approach, The first step was the preparation of green precursor solution by dissolving the raw materials. Then the precursor solution was dried at room temperature for 2 days and heated to 338K for 12 h. After that it was heated at 773K for 1 h. for carbonization of the dried powder. Thus in this step sucrose converted to carbon, zirconiumoxychloride to zirconia and boric acid to boria. Finally carbothermal reduction of oxides to carbides and borides was taken place by heating at 1873 and 1973K for 3 h. **Scheme 4**.

For the preparation of carbon fiber reinforced silicon carbide, carbon fiber tow was washed properly with acetone. Next these fibers were vacuum impregnated with precursor solution of different matrices like SiC, SiC + ZrB_2 , SiC + ZrC , SiC + ZrO_2 . Then

Scheme 4 Reaction mechanism of production of Carbon fiber reinforced silicon carbide composite.

SiC + TiO₂ (Mixture), 3:1 and 6:1

Co milling

time:	5h
medium:	Ar

TiO₂/SiC, ceramic mixture

Scheme 5 Experimental set up for high energy ball milling process.

it was dried at room temperature for 6 h and after that at 338k for 2 h for removal of excess water. Then the dried samples were carbonized at 773k for 1 h for the conversion of sucrose to carbon. This sequence of vacuum in pregation, drying and carbonisation were repeating for 6 times to improve the density of the composites. The samples were heated at 1873k and 1973k for 3 h in argon atmosphere. The density of the prepared composites has been measured using Archimedes principle.

Characterization

First thermogravimetric analysis was done for the green powder to know the change of reactants on heating. With the lowering of temperature, the green precursor attributed towards the amorphous nature of obtained carbon materials. The crystalline characteristics was reported by using XRD. SEM analysis of the compound was also done to know the structure.

SiC- TiO₂ Ceramic Composites

In another research work ceramic composites were again synthesize by environment sustainable method for tribological studies (Briscoe and Sinha, 2008). Polymers have very interesting properties and lighter than metal and ceramics. But pure polymer was not suitable for tribological application due to its low strength and low wear resistant. The high hardness of SiC were able to reduce polymer wear. The toughness of SiC can be improved by adding TiO₂ which can also improve the wear resistant (Zum Gahr, 1998). In this work a mechanochemical method was applied for preparation of SiC- TiO₂ ceramic powder which can be used as filler in polymer tribosystem.

Experimental

A Novosibirsk Corp. Activator 2S mill (Novosibirsk, Russia) was used for all high-velocity ball milling experiments. The steel reaction vessels(10 mm diameter) were taken to dry in argon atmosphere with a ball to powder ratio is 10:1.Milling time was 5 h and conducted at 1100 rpm. 10 gm of sample were taken into each reaction vessels. Series A composed of 6:1 weight ratio of SiC- TiO₂ and in series B the ratio was 3:1 **Scheme 5**.

Characterization

The obtained final products were used in powder X-ray diffraction (XRD) on a Philips X'Pert instrument with CuK α source between 10 and 90° 2 θ with a step size of 0.05° to analyze the morphology. SEM-EDS measurements were also done by using Hitachi S 4700 instrument at 20 kV and at a magnification of 10,000 X. For EDS analysis a Noron VANTAGE microanalysis system was used.

Conclusion

Now a days in any developing country a common word is being echoed in every industrial sector i.e., "Green Technology". Due to different types of production techniques there have been many greenhouse gases released into the atmosphere since 100 years. This is the main cause of the phenomena 'global warming'. And now for our sustainability, it's the time to save our planet from the effect of these harmful gases. In a near future the industries around the world would achieve a development in production which

has less impact on environment. Green synthesis of materials not only reduce the pollution of environment, also it can lower the impact of manufacturing at each and every stage. Environment sustainable production focuses on mitigation of greenhouse gas emissions, effluents, accidents, use of virgin and nonrenewable energy resources, life cycle cost, product and services.

Introduction

Global Transport Scenario

The entire world's day to day transport (including light-duty and heavy-duty vehicles) vastly depends on two important fuel resource viz. diesel and gasoline. The world's statistical data portray that 947 million light-duty cars and 335 million commercial vehicles were operational in 2015 which was 2 times higher compared to the number of vehicles ten years back ([Annual Energy Outlook, 2018, EIA](#)); thus, indicating a significant demand growth of such automobile liquid fuels.

Moreover, an article published in [International Energy Outlook \(2016\)](#) disclosed that energy consumption has been 30.472 trillion kWh in 2012 and will reach to 45.415 trillion kWh in 2040 ([IEO, 2016, EIA](#)) in the transport sector. Countries like India, Africa, China and other parts of Asia accounted for about 61% share in global transportation energy. The published report also encompasses the fact that among the personal mobility modes of transport, light-duty vehicles occupied 44% of global transportation energy; while heavy transports (cargo/shipment) consumed 39% of total energy; whereas goods trucks shared 23% followed by marine vessels (12%), rail and pipeline (a combined 4%). Aircraft and buses including 2 or 3 wheeler vehicles consumed 11% and 6% of global transportation energy ([IEO, 2016, EIA](#)). Therefore, it is quite evident that road transportation sector has major share in global transport energy.

Fuel Prices, Fuel Depletion and Climate Change

The whopping mandate of liquid fuel in public transport, growth in the financial market and global trade has elevated the price of crude oil vis-à-vis petroleum products viz. gasoline and diesel. It has been reported elsewhere that the key fuel source in surface transport is gasoline in OECD (The Organization for Economic Co-operation and Development) countries; whereas, in non-OECD countries like India and China, diesel has been the major transport fuel. Likewise, statistics show that China and India became world's largest crude oil importer; this depicts the fact that these countries are most affected by the market prices of the crude oil.

The present scenario also illustrates the imbalance between demand and supply chain caused due to high exploitation of fossil fuel for technological and economic advancements. Since oil, natural gas and coal are finite natural resources and its declination is inevitable from the geological point of view, a concern existed regarding exhaustion of these non-renewable fuels. Furthermore, if the same extraction rate continued the worldwide crude oil reserve will last for only another 50 years.

Moreover, the environmental stability was not only disturbed due to depletion of fossil fuel, but the dreadful emission resulting from these natural fuels, possesses a grave threat to the entire mankind. Consequent greenhouse gas (GHG) emission leading to global warming and climate change has become global apprehension in the present situation. The average universal temperature has increased from 1.8 to 4.0°C owing to GHG emissions. Thus, it could be well understood from the statistical data

that with the increase in the existing fleet to satisfy the comfort of the society, the fossil fuel consumption will increase which will also putrefy the atmosphere proportionately.

Additionally, other toxic engine emissions involving NO_x (nitrous oxides), SO_x (sulfur oxides), HCs (hydrocarbons) and PM (particulate matter) causes harm to the environment by depleting the ozone layer, causing acid rain, contributing to smog formation and disturbing human health profoundly. Therefore, various countries implemented environmental policies viz., United National Framework Convention on Climate Change (UNFCCC) and the Kyoto Protocol that mandated engine modifications or alterations in fuel quality to overcome these detrimental effects. Thus, the researchers are struggling to find efficient fuel substitutes or investing to develop energy-efficient equipment in order to tackle ever-increasing oil prices and environmental pollution.

Fuel Blending

Green Fuel Blending With Gasoline

To restrict the polluting emission from gasoline (for example 1098 million metric tons of CO₂ only in US), gasoline blending with green fuel has recently attracted the attention of various researchers and policy makers.

Green gasoline derived from fermentable sugars of corn, sugarcane, sugar beets, barley, sorghum, cassava and other agricultural biomass acted as an efficient green fuel substitute in the spark-ignition engine by virtue of its high octane value, thereby reducing emission of harmful pollutants compared to conventional gasoline. In 2007, legislation was enforced by Renewables Fuels Standard that necessitated blending of gasoline with 10% of bioethanol without engine modifications; statistics also showed that 96% of all gasoline vehicles in the USA could run on gasoline blended with 10% bioethanol (derived from corn).

The United States became the largest fuel-ethanol producer (15.8 billion gallons) followed by Brazil (7.6 billion gallons), China (0.87 billion gallons), India (0.28 billion gallons) in 2017 ([Ethanol fuel production in top countries, 2017](#)). More recently, a report by the International Energy Agency ([IEA predicts growth in global ethanol production through 2023, 2018](#)) on market analyses of renewable fuels predicted that ethanol would occupy two-third global share in the growth of conventional biofuels within 2023.

Similarly, bio-methanol (BM) is also known for its blending synchronization with gasoline in SI engines. An article published by IEA reported the tradition of methanol use as a transportation fuel in the US and China where many refueling stations employ M3 (3% methanol) to M85 (85% methanol) blends for road transports.

Therefore, BM can serve as an efficient fuel additive which can be produced from chemical/biochemical conversion routes using different feedstocks viz., animal trash (cattle manure) and agricultural wastes.

However, production of BM through chemical route involves gasification of carbohydrates into carbon monoxide and hydrogen that undergo catalytic reaction to produce methanol. Moreover, BM production from biomass gasification requires additional steps like pretreatment, gas cleaning (removing tar, soot, alkali metals) and gas conditioning (removing methane and other hydrocarbons). Unlike gasification, methanol can also be directly obtained from fermentation of sugars and starch (biochemical route) without incurring additional processing costs.

Green Fuel Blending With Diesel

Biodiesel is a competent renewable, green substitute for conventional diesel fuel that can effectively reduce the harmful engine exhausts. Sources of biodiesel production are transesterification of vegetable oil and esterification of fatty acids using methanol/ethanol for generation of methyl/ethyl esters of fatty acids ([Pradhan and Chakraborty, 2018](#)). Biodiesel is well known for its increased oxygenation ability that facilitates complete combustion of fuel, thereby reducing the detrimental emanation of CO from the diesel engine. According to the statistical data published, USA projected a production of 1 billion gallons of biodiesel within 2025 ([Leading biodiesel producers worldwide in 2017, by country in billion liters, 2017](#)). It has been also reported that in 2050, green-fuels like biodiesel would significantly replace petroleum-based fuel and would be able to meet 40%–60% of the total energy demand of the world. This growth will not only improve the economy of the non-oil producing countries by plummeting their needs on imported crude petroleum fuel but will also offer great enticements to the agricultural sectors and rural economy.

On the other hand, bio-alcohols viz. ethanol and butanol not only serve as gasoline additives in SI engines but can also improve the burning characteristics of diesel fuel in CI engine. Alcohol-diesel blends have efficacy in heightening fuel cetane number, reduces particulate matter (PM) emission and also helps demand suppression of petroleum-based fuel.

However, the response for hydrotreated vegetable oil (HVO) or green diesel is competitive to bio-alcohol and biodiesel. They have better shelf life i.e., less susceptible to oxidation, has the potential to be used as unblended feedstock without any alterations to the existing engine designs and a high calorific value similar to diesel. Besides propane is the by-product of this hydrotreated vegetable oil which has huge market demand. Therefore the catalytic hydrotreating of waste and residue feedstock holds a significant share in the production of valuable green fuel.
